Operation is indicated in all patients who exhibit definite signs of progressive cardiac damage, evidence of pulmonary hypertension, signs of congestive failure and those in whom the calculated pulmonary blood flow

is more than twice the systemic flow. It is preferable to advise operation before the development of excessive changes in the pulmonary arterial pressures has taken place.

Patients who develop signs of major cardiac enlargement usually show symptoms of serious difficulty. The large defects may give rise to congestive failure early in life, but the majority of patients develop their symptoms in adult life. If the existing shunt shows a high rate of pulmonary blood flow and relatively normal pulmonary resistance and only moderate pulmonary hypertension, operation is extremely safe. Patients with extremely high pulmonary resistance carry a much more serious prognosis and operation is more hazardous. It is advisable to correct such defects in childhood or early adult life, but infants below the age of one year should be offered operation only when there is evidence of a serious problem. Compensatory interatrial communications should not be closed, except as a part of an over-all procedure in which the primary defect is corrected. When patent foramen ovale is associated with pulmonic stenosis, the correction of the latter is usually the only procedure necessary.

Surgical methods for the correction of atrial septal defects are of two types—closed

Figure 8. A posterior interatrial septal defect is shown before and after closure by the exclusion method. The anterior right atrial wall is approximated to the anterior edge of the defect which deviates the pulmonary venous return entirely into the left atrium.

valve represents another type of atrial septal defect.

Absence of the atrial septum represents failure of development of the primitive anlage of the atrial septa. The persistence of an ostium primum is associated with the failure of the septum primum to establish fusion with the lowermost portions of the atrium. This defect presents a deficiency of tissue just above the tricuspid and mitral valves. Abnormalities or deficiencies of either or both of these valves occur with this defect. A cleft mitral and/or tricuspid valve is the commonly associated lesion. Atrioventricularis communis represents failure of the fusion of the septum primum to the lower portions of the atrioventricular canal, the atrioventricular cushions. The persistent ostium secundum is the most frequent true septal defect and represents failure of development or fusion of the septum secundum with the septum primum.

During the fourth week of gestation, the separation of the atria and the ventricles begins. The sinus venosus enters into what ultimately becomes the right atrium. The septum primum begins its development as a crescentic ridge on the superior and dorsal portion of the single atrium. It grows downward toward the atrioventricular canal. The common atrioventricular channel is gradually divided into right and left channels by the endocardial cushions. The septum primum in the meantime has gradually grown inward and downward toward the endocardial cushions until it fuses with them. Just prior to the union of the septum primum with the atrioventricular cushions, the uppermost portion of the septum primum becomes resorbed so that the two atria are still in free communication. In the meantime the interventricular septum has gradually become more prominent and finally also fuses with the endocardial cushions at a point which is ultimately just below the annulus of the valve rings. The septum secundum then begins to develop just to the right of the point at which the septum primum had initially originated. It arises as a long ridge along the entire dorsal aspect of the atrium and grows ventrally and downward but does not completely close to form a solid wall. The remaining central opening is the foramen ovale which is covered on its left aspect by the inferior remaining portion of the septum primum. This uppermost remaining segment of the remnant of the septum primum does not fuse with the edges of the septum secundum before birth but

remains as a flap-type valve which permits flow from right to left but does not permit flow from left to right. It is only with the assumption of pulmonary function after birth that cessation of flow from right to left allows the gradual fusion of the uppermost portion of the septum primum with the septum secundum, resulting in complete separation of the two atria. From these considerations it is apparent how the various types of defects occur.

Abnormalities in the development of the septum secundum cause the posterior-lying defects to occur. Failure of fusion of the septum primum with the endocardial cushions gives rise to the ostium primum type of defect. Excessive resorption in the septum primum permits the persistence of the foramen ovale. This highly simplified explanation of the developmental aspects of interatrial defects can be expanded to cover the other variations.

In general, the larger the size of the defect the more rapid is the development of symptoms and the greater the amount of the shunt. In the presence of normal pulmonary resistance, the shunt is predominantly from left to right. When the defect is large, the shunt may be in both directions and thus may result in a predominant left-to-right shunt, but with some degree of peripheral arterial unsaturation. Phenomena which increase the pulmonary pressure may cause a reversal of the left-to-right shunt and thus produce transient cyanosis.

When the atrial defect is small, there may be minimal shunting and no symptoms may exist. There is frequently a history of cyanosis, particularly in infancy and in early neonatal life. Cyanosis may be particularly noted during periods of crying, feeding and respiratory infection, but cyanosis tends to be periodic. In a large percentage of patients, no history of cyanosis can be obtained even in the presence of a fairly large shunt. Limitation of exercise tolerance or underdevelopment may be the only sign in early life. Large shunts in infants may produce signs of congestive failure. The onset of symptoms in the majority of patients is noted in late childhood or early adult life. Arrhythmias are common and, with the development of the lesion, signs of dyspnea and fatigue appear.

Physical examination frequently shows bulging of the left precordium. Cyanosis is present when there is an associated lesion, particularly pulmonic stenosis, serious anomalous venous drainage or during periods of

stress. With the development of high pulmonary arterial pressures over prolonged periods, reversal of the shunt may occur and cyanosis may become permanent. The heart is usually enlarged and the characteristic systolic murmur is best heard over the second or third left intercostal space. The murmur of an atrial septal defect is not entirely characteristic and may vary widely in intensity. The pulmonic second sound tends to be loud because of the increased pulmonary flow and increased pulmonary pressure. Fixed splitting of the pulmonic second sound is present in a high percentage of cases. Signs of congestive failure may be present. Electrocardiograms show right ventricular enlargement and/or right ventricular strain. P waves are usually prominent and right bundle branch block of varying degree is the rule in defects of the secundum type. Vectorcardiograms are usually characteristic in primum lesions.

X-ray films of the heart show enlargement of the right atrium and right ventricle. The pulmonary artery and pulmonary vascular markings are prominent and pulsations of the secondary vessels are notable. Angiocardiography shows refilling of the right atrium from the left. In the presence of a pure left-to-right shunt, contrast medium cannot be visualized to pass from the right to the left side.

Cardiac catheterization is usually helpful to make certain no additional lesion is present and to determine the volume of the shunt. The catheter may pass directly into the left atrium or left ventricle, or a left-to-right shunt may be evident by increased oxygenation in the right atrium. The catheter can also enter the pulmonary veins, particularly those on the right. Entrance of the catheter into the pulmonary veins does not necessarily indicate anomalous venous drainage, although abnormalities of the pulmonary venous drainage are commonly associated with the atrial septal defect. By calculation of the right and left ventricular outputs, one may determine the amount of blood which is shunted per minute. In many patients the right ventricular output may be three or more times that of the left. Dye dilution or nitrous oxide techniques permit determination of the site of the shunt and quantitation of the volume of shunt.

Operation is indicated in all patients who exhibit definite signs of progressive cardiac damage, evidence of pulmonary hypertension, signs of congestive failure and those in whom the calculated pulmonary blood flow

is more than twice the systemic flow. It is preferable to advise operation before the development of excessive changes in the pulmonary arterial pressures has taken place.

Patients who develop signs of major cardiac enlargement usually show symptoms of serious difficulty. The large defects may give rise to congestive failure early in life, but the majority of patients develop their symptoms in adult life. If the existing shunt shows a high rate of pulmonary blood flow and relatively normal pulmonary resistance and only moderate pulmonary hypertension, operation is extremely safe. Patients with extremely high pulmonary resistance carry a much more serious prognosis and operation is more hazardous. It is advisable to correct such defects in childhood or early adult life, but infants below the age of one year should be offered operation only when there is evidence of a serious problem. Compensatory interatrial communications should not be closed, except as a part of an over-all procedure in which the primary defect is corrected. When patent foramen ovale is associated with pulmonic stenosis, the correction of the latter is usually the only procedure necessary.

Surgical methods for the correction of atrial septal defects are of two types—closed

Figure 8 A posterior interatrial septal defect is shown before and after closure by the exclusion method. The anterior right atrial wall is approximated to the anterior edge of the defect which deviates the pulmonary venous return entirely into the left atrium.

and open. Closed methods have largely been superseded but are sometimes valuable in defects associated with anomalous pulmonary drainage. Figure 8 shows such a method. When this procedure is used, it must be ascertained that no shunt remains

before operation is completed. Atrial defects of the ostium secundum type may be multiple and highly variable in location. Associated anomalies of the pulmonary venous return are common as are hypertrophied valves of the inferior vena cava. By direct visualization of the defects by means of an incision into the right atrium, the defects of the ostium secundum type can be approximated by direct suture (Fig. 9). Very large defects sometimes require patches to avoid undue tension in the closure. When pulmonary venous anomalies are present it may be necessary to use a patch technique to place the pulmonary veins in the left atrium. If pulmonary veins enter the cava itself, they must be redirected into the left side, usually by reanastomosis to another pulmonary vein.

Defects of the atrioventricular canal and endocardial cushion defects involve the inferior portion of the interatrial septum and not infrequently the superior portion of the interventricular septum (Fig. 10). There may be associated clefts in the mitral and tricuspid valves. The valvular defects are

Figure 10. A, Operative view of ostium primum atrial defect (cushion defect) showing a cleft mitral valve seen through the atrial septal defect. B, Closure of mitral cleft by sutures. C, Repair of atrial defect using a patch (sponge or plastic cloth).

corrected by approximating the edges of the cleft with fine sutures. A patch must usually be used to close the defect of the atrial septum because of the rigidity of the tissue in the region of the inferior margin of the defect. The repair may have to include approximation of the upper portion of the ventricular septum as well.

Following repair of atrial defects complete closure is the rule. Defects of the secundum variety carry minimal risk. Endocardial cushion defect repair carries increased hazard, but the mortality rate is still low except in the more complex types of atrioventricular canal. Following repair, normal hemodynamics are obtained and prognosis is excellent.

INTERVENTRICULAR SEPTAL DEFECTS

Ventricular septal defects may exist alone or in association with other lesions. Such defects may be single or multiple and occupy a position either in the membranous or muscular septum. The high lesions lie immediately beneath that portion of the ventricular septum which joins the aortic root and immediately inferior to the leaflets of the aortic valve. In some cases there is associated aortic insufficiency. When defects of the interventricular septum exist there is considerable variation in the right ventricular pressure, depending upon the size and location of the defect. The lesions can be divided into groups on the basis of the degree of elevation of the pulmonary pressure. In the severe forms the right ventricular and pulmonary pressures approach or exceed the aortic pressure. When the pressures in the right ventricle are only moderately elevated there may be no symptoms or symptoms may develop only later in life. Frequently in the mild forms there is no manifestation of the abnormality except for the murmur and such patients may live to a considerable age without major physical restriction. Patients with moderate to high pulmonary pressures tend to have frequent respiratory difficulty, particularly recurrent pulmonary infection and limitation of exercise tolerance. It has been pointed out by Taussig and others that those patients who have only slight elevation of their pulmonary pressure early in life tend to show little change on recatheterization later in life. Those patients who have more severe elevations in pressure early in life tend to have increasing pressures with age.

The principal diagnostic features of the more severe lesions include general underdevelopment, susceptibility to respiratory in-

fections, absence of cyanosis when pulmonary pressure is less than systemic, and symptoms of congestive failure. Physical signs are cardiac enlargement, a harsh systolic murmur which is best heard in the fourth left intercostal space and a loud pulmonary second sound. X-ray examination shows a cardiac silhouette which is globular in shape with enlargement of both ventricles. The pulmonary artery tends to be large and prominent. The lung fields are increased in vascularity. Cardiac catheterization shows an increase in the oxygen tension in the right ventricle and increased pressure in the right ventricle and pulmonary artery. A small gradient may exist between the ventricle and the pulmonary artery without organic obstruction because of the high rate of flow. Nitrous oxide and dye dilution techniques give evidence of a shunt at the ventricular level. Angiocardiography shows refilling of the right ventricle and pulmonary arteries. A filling defect may be present in the right ventricle in some patients. Electrocardiographic changes show biventricular enlargement or right ventricular preponderance.

Interventricular septal defects are corrected under direct vision by open cardiotomy. The right ventricle is incised and the area of the septum is exposed. Cardiac arrest is not necessarily employed. The entire septum must be inspected to be sure multiple defects are not present. Frequently the septal defect lies beneath the leaflet of the tricuspid valve. The papillary muscle may be cut to permit retraction of the tricuspid valve to properly visualize the defect. The bundle of His traverses the medial inferior border of the right side of the defects of the membranous septum. Closure of this portion of the defect is accomplished by placing interrupted sutures in the left side of the septum to avoid the bundle (Fig. 11). It may be necessary to use a patch to secure adequate closure without tension. In thinned out areas of the septum the sutures are buttressed by tying them over Teflon felt or cloth. When very high pressures are present in the right ventricle it may be undesirable to completely close the defect primarily. In such instances a fenestrated patch is used to permit readjustment of pressure during the initial postoperative period. The small openings in the patch close over in a period of two to four weeks, allowing for readjustment of dynamics during this interval. A flap valve mechanism can also be employed for this purpose.

Complete heart block has been a compli-

Figure 11 Interventricular septal defect partially closed by sutures under direct vision.

cation of the closure of interventricular septal defects and is a serious problem when it occurs. When caused by a suture placed through the bundle of His, removal of this suture will usually restore normal rhythm. Following closure of the defect in the membranous septum, an electrode is routinely implanted into the myocardium which will permit the use of an artificial pacemaker if complete heart block occurs. A second electrode is sutured in the chest wall. Both electrodes are insulated, except for the terminal portion, so that stimulation is delivered only to the heart muscle. If asystole or a very slow idioventricular rate supervenes, contraction of the heart may be maintained at an effective and optimal rate by the artificial pacemaker. With increasing experience, the incidence of heart block has markedly decreased. Operation is advised in all patients who show symptoms, increasing cardiac size, large shunts or high right ventricular pressures. Operative risk is now low and constantly decreasing, except in patients with very high pulmonary pressures and high pulmonary resistance. Failure to obtain complete closure is not common.

TRANSPOSITION OF THE GREAT VESSELS

Transposition of the great arteries is a common congenital malformation. Relatively few individuals with this anomaly survive to late childhood and a large percentage of such patients die within the first few months

of life. In complete transposition, the aorta rises from the right ventricle and the pulmonary artery from the left ventricle. In order to maintain life, there must necessarily be communication between the two sides of the heart. The usual shunts are maintained through one or more of the following: interatrial septal defects, interventricular septal defects, patent ductus arteriosus or transposition of the pulmonary or systemic veins.

Signs and symptoms of this malformation are usually manifest shortly after birth. Cyanosis, difficulty in respiration, progressive cardiac enlargement and congestive failure are the notable features of this disease. Cyanosis tends to become more intense with increasing age. If oxygenated blood from the pulmonary artery enters the aorta by way of the patent ductus arteriosus, the lower extremities are less cyanotic than the upper. Closure of a patent foramen ovale or patent ductus arteriosus in the neonatal period may produce a sudden deterioration of the patient. The causes of death are cardiac failure and anoxemia.

Physical examination shows increasing heart size beginning shortly after birth. Frequently, there is bulging of the precordium. The apex is displaced laterally and there may be systolic or diastolic murmurs which are not characteristic and there may be no murmurs present. Signs of congestive failure may be noted early.

On x-ray films the heart is enlarged, although immediately after birth it may be normal in size. The pulmonary conus is small or absent. The shadow at the base of the heart is narrow in the posteroanterior view, but in the left anterior oblique position or in the lateral position the shadow is quite wide since the pulmonary artery and the aorta lie over each other. Pulmonary vascular markings are greatly increased. Angiocardiography shows immediate filling of the aorta from the right side, previous to filling of the pulmonary artery, and the aorta is anterior in origin.

The electrocardiogram shows right ventricular enlargement, but this is not constant. Cardiac catheterization demonstrates communication of the aorta with the right ventricle.

Complete correction of transposition has not been entirely solved. Partial correction of the defect has given marked benefit in many patients. The most satisfactory technique available with the least risk at the present time would appear to be the transposition of the inferior vena cava to the left

atrium and the anastomosis of the right pulmonary veins to the right atrium. In the second stage the remaining venous return can be transposed and the atrial intercommunication closed. In this way complete transposition of the venous inflow can be accomplished. The right ventricle then functions as the left, serving the systemic circuit. Following the first stage of this procedure, improvement has been so striking in many cases that complete correction has been delayed.

Attempts at a one-stage correction of transposition have not yet been successful. Using extracorporeal circulation, attempts have been made to transpose the arterial outflow, but these have not been satisfactory. A single-stage procedure to bring the caval venous return to the left side and the pulmonary venous return to the right side has been outlined. The interatrial septum can be removed and a patch of saddle-shaped configuration sutured around the orifices of the pulmonary veins and over to the edges of the tricuspid valve. This would bring the pulmonary flow to the right side. Through the remaining orifice of the opened interatrial septum the caval blood could flow to the left side. This is a highly promising procedure which may be successful in the future.

DISEASES OF THE PERICARDIUM

The common diseases of the pericardium may be classified as follows:

- I. Pericardial cyst and diverticulum
- II. Acute pericardial effusion
 - A. Serous or fibrinous
 - B. Hemorrhagic
 - C. Purulent
- III. Chronic pericarditis
 - A. Adhesive pericarditis
 - B. Constrictive pericarditis
- IV. Tumors of pericardium
 - A. Fibroma
 - B. Lipoma
 - C. Mesothelioma
 - D. Sarcoma
 - E. Teratoma

Pericardial cysts are thin walled and contain serous fluid. They are lined by a flattened mesothelium. They are most commonly seen at the pericardiophrenic angles, but may occur at any point in association with the pericardium. A cyst with a direct opening into the pericardium proper is known as a *diverticulum of the pericardium*. The walls of the cyst are fibrous connective tissue and are lined with flattened

mesothelium. Pericardial cysts tend to remain benign. They vary in size from minute structures to cysts which may occupy the major portion of the chest.

Until the cyst becomes extremely large there are no symptoms. Chest pain or pressure may occur. Physical findings may be within normal limits or there may be dullness to percussion and signs of pulmonary compression.

On x-ray examination the majority of the pericardial cysts are found to occur on the right side near the junction with the diaphragm. Their borders tend to be rounded and smooth and may change their shape with the position of the patient. When they lie in the region of the aortic arch or root, they are frequently confused with an aneurysm or tumor of the lung.

Therapy consists of excision, even in the absence of symptoms. Surgical treatment is recommended upon the discovery of the lesion because, until exploration is carried out, it cannot be positively identified as a pericardial cyst. No lesion in this position can be considered entirely benign without biopsy since other lesions in this area are malignant. Danger of infection or continued pressure remains until removal is effected.

Acute serous or fibrinous pericardial effusion may be associated with rheumatic or viral agents. It may also be of metabolic and nonsuppurative bacterial origin. Signs and symptoms may be absent but usually include fever, tachycardia, pain and shortness of breath. The symptoms may be confused with those due to pneumonia or acute abdominal states. Pain tends to be periodic, sharp, and stabbing in character or pleuritic. As larger amounts of fluid accumulate, the pain may disappear, whereas if the effusion remains predominantly fibrinous, the pain may persist for considerable periods with remissions and exacerbations. The rapid accumulation of large amounts of fluid may lead to cardiac tamponade (Fig. 13).

Cardiac tamponade gives rise to the signs of acute cardiac compression which are a quiet heart, elevation of the venous pressure and decreasing arterial pressure. The heart sounds are distant. Signs of peripheral vascular collapse and a paradoxical pulse may be manifest. The heart shadow is normal or enlarged on fluoroscopy and shows less than a normal amount of pulsation.

Tamponade is seen frequently in association with penetrating injuries of the heart and accompanies the acute accumulation of blood in the pericardium. Decompression of

Figure 12 Acute cardiac tamponade showing compression of venae cavae and pulmonary veins. The compression also interferes with diastolic filling of the ventricles.

Figure 13 Constrictive pericarditis. The heart is encased in a thick, calcified pericardium.

the pericardium is a lifesaving measure. This may be accomplished by needle aspiration or surgical drainage. Aspiration is performed by the paraxiphoid or the parasternal route. Pericardial aspiration always carries the risk of further laceration of the coronary artery or the atrium and further intrapericardial bleeding. The use of intravenous fluids may give clinical improvement in acute cardiac compression and maintain life until pericardial aspiration or drainage can be performed.

Surgical decompression of the pericardium may be accomplished either through a small anterior thoracotomy incision made just to the left of the sternum or through a paraxiphoid extrapleural approach. Incision of the pericardium, with excision of a small window, permits external drainage or excision of a portion of the pericardium in its intrapleural portion and institutes drainage into the pleural space.

Conservative aspiration therapy is frequently successful and is particularly useful in serous pericarditis. In tamponade due to trauma, aspiration combined with the use of intravenous fluids and blood replacement will often be associated with spontaneous cessation of the bleeding. If, after two attempts at aspiration, the signs of cardiac compression recur, or if there is serious bleeding into the pleural space with excessive blood loss, immediate operation should be carried out. The rapid replacement of blood loss by pressure transfusion is ne-

cessary in some subjects to gain sufficient time to get the patient to the operating room.

If continued cardiac compression occurs from bleeding, the heart is approached through the anterior fourth intercostal space on the left. The pericardium is opened and the blood removed. The wound in the heart is controlled by pressure and then closed with multiple silk sutures. Excessive delay by continued pericardial aspirations in the patient who shows signs of rapid recurrence of cardiac compression after the first pericardial tap is dangerous. Failure to evacuate all of the blood from the pericardium and to keep the pericardium dry in the post-traumatic period frequently gives rise to signs of chronic cardiac compression. This must be relieved by pericardiectomy at a later time.

Chronic compression is due to dense fibrosis of the pericardium, which prevents adequate venous filling of the heart by constriction of the venous pathways or the ventricular chambers (Fig. 13). The most common cause of constrictive pericarditis is tuberculosis, but this affection also is seen after hemopericardium. Chronic cardiac compression is characterized by a quiet heart which, though often normal in size, may be enlarged and by elevated venous pressure and enlargement of the liver associated with ascites. Fluoroscopy shows a

art shadow with little movement or dimin-

ished pulsation. Kymograms confirm the decreased cardiac excursion. Extensive calcification may or may not be present in the pericardium. The presence of calcium in the pericardium is not diagnostic of constriction.

Dyspnea, venous distention, cyanosis, pain in the right upper quadrant and swelling of the abdomen are common symptoms. Heart sounds are distant to normal. Murmurs may be present. A pericardial knock is frequent. The signs of abdominal and pleural fluid and ankle edema are common. The liver is enlarged. Liver function may be markedly impaired; venous pressures are elevated. Cardiac catheterization shows relatively characteristic pulse tracings.

Complete resection of the anterior pericardium with freeing of the superior and inferior cavae, the pulmonary veins, the diaphragmatic surface of the heart and both ventricles can be done in the majority of cases as a single procedure. This may be performed through a midline sternum-splitting incision or a transverse bilateral thoracotomy incision. In more severe cases, it may be necessary to do the operation in two stages. The pericardium is densely adherent to the myocardium and calcification may extend through the pericardium into the muscle of the heart itself. The removal of the pericardium always proceeds from the apex to the left ventricle, freeing the entire left ventricle, left atrium, then the right ventricle, right atrium and finally to the cavae. If both right and left ventricles should be badly compressed and one relieves only the right ventricular constriction, fatal acute pulmonary edema may occur.

A high index of suspicion is necessary to make the diagnosis of chronic cardiac compression, which is frequently confused with renal disease or primary liver disease. Swelling of the abdomen and the scrotum with relatively little ankle edema, congestive failure without an adequate explanation, such as valvular disease or coronary artery disease, should make one suspect constrictive pericarditis.

Pericardial biopsy should be performed in all patients in whom there is suspected tuberculous pericarditis or acute pericarditis of unknown origin, in order to establish the cause. If at the time of biopsy there is already evidence of thickening of the pericardium, pericardiectomy can be carried out at this time. If the lesion is tuberculous, specific treatment with streptomycin and other antituberculous drugs is indicated.

Pericardiectomy carries a relatively low

risk. Complete relief of symptoms with disappearance of ascites and return of adequate cardiac function is to be expected. When the constriction has been present for a long time before operation, an interval of three to six months may elapse before the patient manifests his maximal improvement. If pericardiectomy is carried out in the earlier phases of the disease and is adequate in its extent, an immediate return of normal pressures will result.

Suppurative pericarditis is associated with staphylococci, pneumococci, actinomycotic and mixed tuberculous infections.

The symptoms are those of acute pericarditis associated with fever, sweating, shock and sometimes cardiac tamponade. Physical signs are fever, rapid pulse, low systolic and high diastolic pressure and congestive failure. The area of cardiac dullness may be increased and a friction rub may be transiently present. Paradoxical pulse and distention of the neck veins with increased venous pressure are noted if tamponade is present.

X-ray examination usually shows an enlarged cardiac shadow characteristic of fluid in the pericardium. Pericardial aspiration will reveal the presence of purulent exudate which should be cultured aerobically, anaerobically and on media for tuberculosis and fungi.

Purulent pericarditis may be treated by repeated needle aspiration and instillation of the proper antibiotic both locally and systemically. Open drainage of the pericardium is preferable. A window is excised from the pericardium after extrapleural exposure of the pericardium. A Penrose drain is left in the pericardial sac for irrigation with saline and antibiotic solutions. The proper antibiotics are also given systemically.

MITRAL STENOSIS

Mitral stenosis has long been recognized as being primarily associated with rheumatic fever, although it also exists in the congenital form. It is most common in young adults and females are affected more often than males. From the time of the initial attack of rheumatic fever until the development of symptoms of mitral stenosis, there is frequently a lapse of many years. Approximately 50 per cent of the patients who have outspoken mitral stenosis give no history of having had previous rheumatic fever in the classical form. The course of the disease tends to be slowly and steadily progressive, beginning with dyspnea on strenuous exer-

Figure 12. Acute cardiac tamponade showing compression of venae cavae and pulmonary veins. The compression also interferes with diastolic filling of the ventricles.

Figure 13. Constrictive pericarditis. The heart and venae cavae are surrounded by dense, thick, fibrotic and calcific pericardium. The ventricular musculature is invaded by fibrous tissue and calcium deposition.

the pericardium is a lifesaving measure. This may be accomplished by needle aspiration or surgical drainage. Aspiration is performed by the paraxiphoid or the parasternal route. Pericardial aspiration always carries the risk of further laceration of the coronary artery or the atrium and further intrapericardial bleeding. The use of intravenous fluids may give clinical improvement in acute cardiac compression and maintain life until pericardial aspiration or drainage can be performed.

Surgical decompression of the pericardium may be accomplished either through a small anterior thoracotomy incision made just to the left of the sternum or through a paraxiphoid extrapleural approach. Incision of the pericardium, with excision of a small window, permits external drainage or excision of a portion of the pericardium in its intrapleural portion and institutes drainage into the pleural space.

Conservative aspiration therapy is frequently successful and is particularly useful in serous pericarditis. In tamponade due to trauma, aspiration combined with the use of intravenous fluids and blood replacement will often be associated with spontaneous cessation of the bleeding. If, after two attempts at aspiration, the signs of cardiac compression recur, or if there is serious bleeding into the pleural space with excessive blood loss, immediate operation should be carried out. The rapid replacement of blood loss by pressure transfusion is neces-

sary in some subjects to gain sufficient time to get the patient to the operating room.

If continued cardiac compression occurs from bleeding, the heart is approached through the anterior fourth intercostal space on the left. The pericardium is opened and the blood removed. The wound in the heart is controlled by pressure and then closed with multiple silk sutures. Excessive delay by continued pericardial aspirations in the patient who shows signs of rapid recurrence of cardiac compression after the first pericardial tap is dangerous. Failure to evacuate all of the blood from the pericardium and to keep the pericardium dry in the post-traumatic period frequently gives rise to signs of chronic cardiac compression. This must be relieved by pericardiectomy at a later time.

Chronic compression is due to dense fibrosis of the pericardium, which prevents adequate venous filling of the heart by constriction of the venous pathways or the ventricular chambers (Fig. 13). The most common cause of constrictive pericarditis is tuberculosis, but this affection also is seen after hemopericardium. Chronic cardiac compression is characterized by a quiet heart which, though often normal in size, may be enlarged and by elevated venous pressure and enlargement of the liver associated with ascites. Fluoroscopy shows a heart shadow with little movement or dimin-

normal sinus rhythm should suggest immediate evaluation for operative intervention. Progression of symptoms with increasing dyspnea on exertion and the development of peripheral embolism, major hemoptysis or signs of pulmonary congestion are indications for operation. The presence of acute rheumatic fever, subacute bacterial endocarditis or other diseases with a more un-

stenosis is a Patients with evaluated in

relation to the possibility of correcting all valvular lesions simultaneously, if possible, or in stages if necessary.

The mitral valve is usually most accessible through the left side of the chest and the

left atrial appendage is used as the site through which the index finger can be introduced into the left atrium to palpate the valve. The valve is then opened along the lines of the commissures, either by fracture of the valve with the finger, or with a knife which is advanced along the finger to engage the commissure and to incise it. The chordae tendineae below the cut edges of the valve are separated so that the valve leaflets can move freely (Fig. 15). The valve orifice, which is usually smaller than the tip of the index finger, is opened through a width of two to two and one-half fingers. The appendage is amputated to prevent the formation of thrombus. Any clot which may be present in the atrial appendage is re-

Figure 14 Mitral stenosis. The relation of the normal valves is illustrated. The progressive fusion of the mitral leaflets is shown. The lower figure depicts stenosis with a posterior orifice, an anterior orifice and stenosis combined with a teardrop type of mitral insufficiency.

tion and excessive fatigue, gradually increasing to dyspnea on moderate to minimal exertion. Because of the slow and insidious progress of the disease, the patient is frequently not fully aware of how limited his activities have become until he is no longer able to carry on his occupation.

Episodes of palpitation, pulmonary edema, paroxysmal nocturnal dyspnea and hemoptysis are common symptoms. Liver enlargement and congestion are associated with right upper quadrant discomfort. The occurrence of atrial fibrillation is frequent. In the later stages of the disease, peripheral edema becomes manifest.

The mitral valve is composed of a major anteromedial and a smaller posterolateral leaflet. The valvulitis produced by rheumatic fever tends progressively to narrow the mitral orifice. The sealing together of the two leaflets in a fibrous union begins by the formation of fibrinous adhesions which bridge the commissures at the edges of the leaflets. As vascularization and organization progress, the orifice is gradually narrowed. The area immediately adjacent to the valve orifice is thickened and calcified. The edges of the chordae tendineae also become fused as well as thickened and shortened. In spite of these changes, the peripheral zone at the valvular annulus tends to remain quite flexible and it is this factor which makes it possible to restore normal valvular function by operation even though the valve may be stiff, thickened and even calcified toward its central portion. When this hingelike action is preserved peripherally, an incision in the commissural area will permit the valve to open widely and to close normally. Incisions at points other than the commissures into either leaflet produce mitral insufficiency of varying degrees. Cutting or fracturing the anterior leaflet produces larger amounts of insufficiency than do lesions of the posterior leaflet because the anterior or aortic leaflet guards the outlet tract of the left ventricle (Fig. 14).

The normal mitral orifice is approximately 4 to 6 sq. cm. in area. When the total area available for flow has been narrowed to less than 2.5 sq. cm., the patient notes progressive symptoms. When it approaches 1 sq. cm., the patient's exercise tolerance is markedly decreased.

Physical examination shows signs which are frequently limited to the heart and lungs. The heart is not greatly enlarged unless other complicating valvular lesions are present. The enlargement of the heart is

predominantly of the right ventricle and left atrium. This may be manifest either as slight enlargement to the right or left side of the chest. As the right ventricle enlarges, it rotates toward the left, moving the apex in that direction. The left atrium enlarges posteriorly and toward the right.

The murmur of mitral stenosis may be extremely difficult to hear. It is characteristically an apical diastolic rumbling murmur with presystolic accentuation. A diastolic thrill sometimes occurs. The first sound is loud and snapping. An opening snap is also audible. If atrial fibrillation is present, presystolic accentuation may not be noted. Systolic murmurs of moderate intensity may also be present even though the lesion may be pure mitral stenosis. In some patients the murmur of mitral stenosis is heard only in the left lateral position. The murmur is accentuated by coughing. The pulmonary second sound is loud. The murmur of pulmonary insufficiency may be present because of dilatation of the pulmonary artery.

The cardiac silhouette may be normal or slightly enlarged. Oblique views will demonstrate enlargement of the right ventricle and left atrium. The left atrial shadow may be prominent on the right border of the heart which shows a double contour. The pulmonary conus is full. The pulmonary markings may be prominent and show pulmonary congestion. Barium swallow usually shows displacement of the esophagus from enlargement of the left atrium.

Cardiac catheterization may show increased pulmonary arterial pressures and high pulmonary capillary pressures. Cardiac output is fixed at relatively low levels. Exercise shows either no increase or a fall in cardiac output since, when the heart rate increases, the time consumed in systole increases at the expense of diastolic filling time per minute. At a given pressure, the amount of blood that will flow through an opening of fixed size is dependent upon the time of diastole.

The electrocardiogram may show no characteristic changes or only prominent P waves. It may show atrial fibrillation and usually will show some signs of right ventricular hypertrophy.

Patients who have a diagnosis of mitral stenosis should be evaluated to determine whether operation will be beneficial. The presence of previous congestive heart failure has not been a contraindication to operation. The development of atrial fibrillation in a patient who has previously had a

be greatly improved but will have some limitation in extreme exercise and the remaining 5 per cent will show little or no improvement. In this latter group, technical difficulties such as contraction of the entire valve annulus, the presence of an extremely stiff valve which fails to function properly after being opened, the production of serious mitral insufficiency and the inability to secure adequate separation of the chordae are the principal causes of failure. In the terminal group in which there is failure which is not controllable by medical management, operative mortality is approximately 25 per cent and in this group the over-all good results fall sharply, although many patients may obtain considerable improvement even though the ability of the myocardium to regain a normal state appears to be somewhat limited. The operative results may also be compromised by pulmonary changes which are no longer reversible, but this is rare.

MITRAL INSUFFICIENCY

It was formerly taught that some degree of mitral insufficiency was an almost constant accompaniment of mitral stenosis. Exploration of the living heart, however, has shown that this is not necessarily correct. Mitral insufficiency produces a decreased cardiac output and increases the work of the left ventricle, since a portion of the blood which would be normally ejected through the aorta is lost by backward flow through the incompetent mitral valve. This leads to increased pressure in the left atrium similar to that which occurs in mitral stenosis. Small degrees of mitral insufficiency appear to be consistent with a long life expectancy. Mitral insufficiency may be primary, or secondary to another disease which produces major left ventricular enlargement, such as aortic insufficiency.

The symptoms are similar to those of mitral stenosis. Bacterial endocarditis is a more common complication of mitral insufficiency than of stenosis. Atrial fibrillation is frequent.

The physical signs associated with mitral insufficiency are a systolic murmur at the apex which may be accompanied by a thrill. There is cardiac ventricular enlargement and a left ventricular lift. The murmur radiates to the axilla and to the back. The pulmonic second sound is loud. Pulmonic insufficiency may be present.

The x-ray shows left ventricular and left atrial enlargement. The left atrium may be gigantic in size and extends far to the right. The pulmonary artery is prominent and there may be pulmonary congestion.

Left heart catheterization may show high left atrial pressures with a large V wave. Regurgitation may be demonstrated by injection of contrast medium into the left ventricle.

Acute dilatation of the mitral annulus may be also associated with acute rheumatic myocarditis and dilatation of the left ventricle. Insufficiency is also caused by deformity of the valve cusps or, in the presence of relatively normal valve cusps, by extreme shortening of the chordae tendineae. Mitral stenosis and insufficiency may coexist. This is characteristically seen in patients in whom there is fusion of one commissure associated with a major deformity of the aortic cusp of the mitral valve in the area of the other commissure. Insufficiency may be particularly severe in this instance if the chordae are shortened.

Many methods for the correction of mitral insufficiency have been devised. Open operation under direct vision without interruption of the cardiac beat is the procedure of choice. The details of the procedure must be altered to suit the particular circumstances which exist in the individual pa-

Figure 16. Mitral insufficiency with dilated annulus. Valve made competent by sutures in annulus

Figure 15 Mitral stenosis. The anterior commissure is being incised by the knife held on the index finger. The insets show the stenotic valve with fusion of the chordae before operation and the separation of the leaflets and chordae

moved prior to insertion of the finger. It is sometimes necessary to enter the heart through one of the pulmonary veins in order to avoid a clot which cannot be removed from the atrial appendage itself

In patients in whom difficulty is experienced in opening the valve satisfactorily, a combined approach may be used. The index finger is inserted in the atrium in the usual way. A dilating instrument is then introduced into the ventricle and guided from above into the mitral orifice by the intracardiac finger. The instrument permits forcible dilatation of the valve orifice under guidance of the finger.

A right-sided approach is desirable in some patients. After a right thoracotomy, the groove between the superior vena cava and the right pulmonary vein is dissected. A finger is introduced into the left atrium just behind the superior vena cava. Since in patients with mitral stenosis the left atrium tends to enlarge far to the right, this gives a good route of access to the mitral orifice.

For these patients with combined lesions of mitral insufficiency and mitral stenosis and those who have had previous operations for mitral stenosis which have not been successful, a direct operation using the heart-

lung apparatus is now advocated. The approach through the right thorax is highly satisfactory, the left atrium can be entered just anterior to the pulmonary veins or through the interatrial septum. Incision of the commissures and separation of the chordae can then be carried out under direct vision. The mitral insufficiency which is present can be corrected.

The postoperative complications associated with mitral stenosis can be divided into those which are primarily associated with surgery of the mitral valve and those which are associated with a major thoracotomy and an operation upon the heart in the presence of cardiac disease. Complications most commonly encountered primarily related to the operation for mitral stenosis are: dislodgment of clots from the left atrium with peripheral or cerebral embolization; inadvertent production of excessive mitral insufficiency with cardiac failure, and reactivation of the rheumatic process, common to all operations for rheumatic heart disease.

Certain complications associated with cardiac and thoracic procedures in general are: hemorrhage, cardiac arrhythmias; atelectasis associated with either retention of bronchial secretions or aspiration, bacterial endocarditis in procedures in which a valve, major artery or myocardium has been incised, pneumothorax due to laceration of the lung during operation or to rupture of an emphysematous bleb, electrolyte imbalance, pleural effusion, acute pulmonary edema, pericardial effusion and tamponade, pulmonary embolism, and renal complications, particularly lower nephron syndrome with oliguria or anuria usually associated with transfusion reaction and hypotension.

The best results are obtained in patients who have pure mitral stenosis as an isolated lesion and who are under fifty years of age at the time of operation. Patients in the older age groups are not excluded from operation but should be very carefully screened. If there has not been prolonged intractable congestive failure and if there is no arrhythmia other than atrial fibrillation, the over-all mortality rate from operation is less than 4 per cent. Fatalities during or following operation result from technical difficulties, such as hemorrhage during operation, embolic phenomena or from pulmonary complications. Of the surviving patients, approximately 80 per cent will have an excellent result and will be able to return to normal activities. Another 15 per cent will

the cusps similar to that in pulmonary stenosis. Aortic insufficiency and stenosis may coexist, although free aortic insufficiency is not common in the presence of severe degrees of aortic stenosis.

Subaortic stenosis is of congenital origin and may be manifest anatomically by a fibrous diaphragm or muscular ridge at a variable distance below the aortic valve. Generalized hypertrophy of the left ventricular musculature in the subvalvular region has also been described as a cause of obstruction to the outlet tract of the ventricle. This appears to be similar in type to that seen in the right ventricle, proximal to the pulmonary valve.

In rheumatic aortic valvulitis, fusion of the commissures begins peripherally and extends centrally, gradually narrowing the orifice (Fig. 18). Calcification is a common accompaniment of the process even in its earlier phases before it has produced severe symptoms. Calcification of the entire aortic ring in the region of the aortic valve may also occur early in the process. Fusion of the valve cusps occurs by a similar process to that of other valvular fusions, that is, with edema, inflammatory exudate, fibrin deposits, gradual replacement and organization of fibrous tissue. This later becomes calcified, but since, unlike mitral stenosis, the periphery tends to become calcific and stiff early in the process, the restoration of flexibility to the valves by commissural division

is less often as satisfactory as in mitral stenosis. In some cases, calcification does not occur or, if present, occurs only in small amounts and late in the disease. This presents a more suitable situation for operation. Fusion of the commissures is not always symmetrical (Fig. 19A).

The earlier phases of aortic stenosis may be asymptomatic. In this stage there is adequate compensation for the moderate degrees of obstruction by left ventricular hypertrophy. However, with continuing cardiac enlargement, conduction defects may develop with the production of arrhythmias. Ease of fatigue, anginal pain, episodes of fainting, dyspnea on exertion and congestive failure are the usual symptoms. Angina pectoris, syncope or congestive failure is an extremely serious prognostic sign. Patients may die in an episode of syncope, in a Stokes-Adams attack or in ventricular fibrillation.

The murmur of aortic stenosis is harsh in character and is usually heard best over the second right intercostal space or the third left intercostal space. It is frequently accompanied by a thrill which is transmitted into the neck. The aortic second sound is decreased or absent. There may be murmurs of associated valvular disease. Cardiac enlargement is present. The blood pressure may be normal or the pulse pressure may be diminished.

X-rays of the thorax show the cardiac sil-

Figure 17 Mitral insufficiency with destruction of a leaflet. Artificial leaflet with chordae which are sutured to ventricle.

tient. When there is generalized dilatation of the annulus, insertion of sutures at selected intervals can narrow the annulus without impinging upon the leaflets of the valve to restore competency of the valve (Fig. 16). In some cases the sutures are preferably placed in the annulus in the region of the commissures and in others these areas should be avoided with the sutures being placed opposite each other at intervals over the circumference of the annulus. In some cases it is necessary to lengthen or shorten chordae tendineae or to place mattress sutures at particular points within the annulus to secure proper approximation. In the presence of extreme calcification or deficiency of leaflet substance the addition of substance may be necessary. Mobilization of the leaflets may be difficult and a leaflet or entire valve may be replaced with silicone rubber or Dacron leaflets (Fig. 17).

This lesion which has been difficult to attack is now becoming one of the standard procedures in which good results are to be anticipated. As in all lesions in which there is major enlargement of the left ventricle, operation is best done before the patient has maximal left ventricular enlargement. Operation should be advised when the patient begins to have symptoms or shows signs of progression of the lesion.

Results of operation are good in patients

Figure 18 Aortic stenosis. The gradual narrowing of the aortic outflow tract is depicted with the associated thickening and calcification of the cusps at the periphery.

who do not have irreversible changes in the left ventricle. Risk is high in patients who have congestive failure which is uncontrollable or who have valves which cannot be satisfactorily mobilized at operation.

AORTIC STENOSIS

Aortic stenosis may be congenital, arteriosclerotic, rheumatic or postendocarditic. Brucellosis has also been suspected as an etiologic agent. The majority of such cases are probably rheumatic in origin and the exact role of arteriosclerosis in aortic stenosis is not entirely clear.

Certain anatomic features of the aortic valve are important to a clear understanding of its pathologic lesions. The root of the aorta is continuous with the anterior aortic leaflet of the mitral valve. The three cusps attach at their inferior margins to the myocardium of the left ventricle. The coronary arteries arise from the right and left aortic sinuses respectively. The noncoronary sinus lies posteriorly and to the right. The left coronary artery passes between the aorta and the pulmonary artery into the atrioventricular groove, at which point it divides into the anterior, descending and circumflex branches. Since the aortic root lies deeply behind the pulmonary artery and has its origin in the myocardium with the ventricle, the annulus of the valve is concealed anteriorly by the outflow tract of the right ventricle.

Congenital valvular aortic stenosis is associated with fusion of the commissures of

stance to one or more leaflets because of associated aortic insufficiency. To avoid the production of aortic insufficiency by operation in pure lesions, it is essential that the division of the commissures be accurately accomplished. When aortic and mitral disease coexist, both lesions are corrected at a single procedure. The results of open operation have been increasingly satisfactory as more experience has been gained.

Some surgeons have continued to use the closed approach to aortic stenosis, either from above through the aortic root, or from below through the ventricle (Fig. 20). Finger fracture combined with dilatation from above has been satisfactory in many instances. Advocates of the transventricular approach believe that satisfactory openings can be obtained by insertion of a dilator through the ventricle and the risk is less than in the other approaches.

It would appear that open operation offers great advantages, particularly in allowing plastic procedures upon the valve itself or total valvular replacement when indicated.

With the advances in the methods for increasing the mobility of the valve and reconstruction of the leaflets by open technique, risk of operation has greatly decreased. Those patients with acquired aortic stenosis who are not in terminal stages have an operative risk of approximately 10 per cent. Patients with severe conduction changes and uncontrollable heart failure have high mortality rates with operation. Operation should be advised when the patient first shows signs of progression of the lesion, for this is already late in the disease.

AORTIC REGURGITATION

Aortic insufficiency is the most treacherous of the acquired valvular lesions. Its causes are (1) congenital, (2) rheumatic, (3) syphilitic, (4) traumatic, (5) subacute bacterial endocarditis, (6) acute bacterial endocarditis, (7) dissecting aneurysm, (8) aneurysm of sinus of Valsalva and (9) cystic medial necrosis without dissecting aneurysm. The onset of serious symptoms may be rapid after production of an acute form of this lesion or may occur only after many years in the chronic forms. In the latter type, symptoms may be manifest early after severe myocardial damage has occurred.

Free aortic insufficiency is usually associated with ease of fatigue, dyspnea, paroxysmal nocturnal dyspnea, edema and angina pectoris. In its early stages, no symptoms may be present. Sudden death due to ar-

rhythmias is common and in those patients with active rheumatic fever there may be severe myocardial damage with impairment of cardiac contraction.

The heart is usually greatly enlarged by the time symptoms are evident. The enlargement is due both to hypertrophy and dilatation of the left ventricle. The early blowing diastolic murmur is usually best heard along the left sternal border and in the second right intercostal space. It may be associated with a systolic murmur even though the anatomic amount of stenosis may be quite insignificant. A ventricular diastolic gallop rhythm is an early sign of failure. A systolic murmur at the apex due to dilatation of the left ventricle is common. A diastolic rumbling murmur at the apex is also frequently associated and represents the Austin Flint murmur of aortic insufficiency in the absence of mitral stenosis. The blood pressure shows elevation of the systolic pressure and a decrease in the diastolic pressure. The pulse is water hammer in type. The abdominal aorta and the vessels in the neck are frequently violently pulsatile.

X-ray examination of the chest shows the characteristically boot-shaped heart when extreme left ventricular enlargement with dilatation and hypertrophy is present. The aorta shows varying degrees of dilatation and, on fluoroscopy, marked pulsation with rapid expansion in systole and collapse in diastole ("aortic rock") is noted.

The electrocardiogram shows left ventricular enlargement and/or strain. There may be abnormalities of ventricular or atrial conduction. Varying degrees of heart block may be present, as well as signs of myocardial ischemia.

Once the patient with free aortic insufficiency, with a diastolic pressure of less than 50, has begun to show signs of congestive failure, the average prognosis is for two years or less of life. If the aortic insufficiency has been rapidly produced by rupture of a cusp or trauma, prognosis is for an even shorter time.

Since the treatment of aortic insufficiency is still in its early phases, the first patient having been treated less than seven years ago, the criteria for operation are changing. Patients should be selected who have evidence of free aortic insufficiency with marked lowering of their diastolic pressure and major cardiac enlargement, and who are beginning to have early signs of progression of their lesion. The majority of patients surgically treated to date have had Austin Flint

houette with evidence of left ventricular enlargement. This enlargement is usually not as great in pure aortic stenosis as it is in aortic insufficiency or in combined aortic stenosis and insufficiency. In valvular aortic stenosis of either the acquired or congenital type there may be some poststenotic dilatation of the aortic root visible on the right cardiac border. Calcification of the aortic valve can frequently be demonstrated in acquired aortic stenosis by fluoroscopy.

Catheterization of the left heart by the transbronchial left atrial or left ventricular percutaneous route shows a pressure gradient between the left ventricle and the aorta and elevation of the left ventricular pressure. In the presence of extreme failure the left ventricular systolic pressure may be lower than expected and this level may be much lower than it had been prior to the onset of failure. Direct aortic blood pressure tracings show characteristic contours in the presence of serious degrees of stenosis. The critical orifice size for the aortic valve would appear to be 0.7 sq. cm.

Patients most suitable for operation are those who show onset of symptoms such as syncope, angina, progressive fatigue, dyspnea or evidence of myocardial failure which responds to intensive medical treatment. Patients who are in the terminal phases of the disease, with advanced failure which cannot be controlled medically, have an extremely serious prognosis with or without operation and should be offered operation only with the understanding that it carries an extremely high risk. Surgical risk is least when the patient is treated at a time when he is showing progression of his lesion with good medical therapy but while he still can be adequately controlled.

Congenital aortic valvular stenosis is the most amenable of the aortic valvular lesions to surgical approach. With inflow occlusion and total body perfusion the aortic valve may be approached either through the right thorax or by midline sternotomy.

Under total body perfusion the aorta is clamped just proximal to the innominate artery and aortotomy is performed just above the valve. The rudimentary lines of the commissures can be identified and the valve opened to essentially normal size after the heart has been filled with blood and the coronary circulation resumed (Fig. 19B). If the incisions are properly made, no insufficiency results and the gradient across the valve is abolished. The risk of this procedure has been extremely low and the results ex-

Figure 20 Closed approach to aortic valve by means of a dilator introduced into the left ventricle.

cellent. The procedure can also be accomplished under hypothermia, but the time safely available under these conditions is short and is less satisfactory. Cardiac arrest by drugs, anoxia or cold may be used, but operation is usually accomplished without these adjuncts.

Subaortic stenosis is treated satisfactorily by an approach to the obstruction through the aortic root. With the patient on cardiopulmonary by-pass the aorta is opened, the normal valve is retracted and the obstruction in the ventricle is visualized and removed by excision. In some cases the area of obstruction may be a considerable distance below the aortic valve, but it can be satisfactorily visualized.

Acquired aortic stenosis offers difficulties in the mobilization of the valve when extensive calcification of the valve is present (Fig. 19A). The direct approach through aortotomy, as in congenital aortic stenosis, has permitted reconstruction of the valve by incision along the commissural lines and removal of the calcific deposits in the base of the aorta to satisfactorily mobilize the valve. In some cases it is necessary to add sub-

coincident lesions such as coarctation are corrected at the operation for aortic insufficiency.

The present surgical correction of aortic insufficiency has followed three general methods: insertion of a rigid prosthetic aortic valve into the distal portion of the descending arch; reconstruction of the valve and/or aortic root, and insertion of cusp valves to replace one or more leaflets. The ball-valve prosthesis has been widely used. It is inserted into the descending aortic arch just distal to the left subclavian artery. This prosthesis is composed of a Plexiglas chamber and a silicone rubber ball. The valve is maintained in position by "multiple point fixation" which utilizes Nylon rings to exert pressure at many individual points around the circumference of the aorta (Fig. 21). The procedure is done through a left thoracotomy incision which gives easy access to the correction of other lesions such as mitral stenosis and coarctation. The mortality rate following this procedure has diminished and at present approximates 5 per cent. Complications following this procedure are uncommon, but embolization and aneurysm formation have been reported. A modification of the ball valve for insertion in the subcoronary artery position has been devised.

Direct procedures upon the aortic valve and the aortic root have been developed to meet the particular anatomic causes of aortic valve leakage. No single procedure is applicable to all types of aortic insufficiency. These procedures utilize extracorporeal circulation to obtain a bloodless aortic root. Midline sternotomy is the usual approach. Before the ascending aorta is opened the chest is filled with carbon dioxide to minimize the danger of trapping air in the heart

with subsequent embolization. After the aorta has been opened the valve is inspected to determine the type of deformity which may be present in the valve leaflets. When the aortic annulus is dilated and the cusps are minimally deformed, removal of the noncoronary cusp and suture of the commissures of the remaining cusps will totally correct the aortic leak (Fig. 22). Similarly, if the noncoronary cusp is markedly deformed and the other cusps are intact, removal of the noncoronary cusp will be curative. In most cases in which the commissures are separated but the leaflets are still mobile, approximation of the commissures by suture produces good results.

When serious deformity of a single coronary leaflet is present, this leaflet can be replaced with a self-sealing silicone rubber leaflet (Fig. 23). In still other instances, substance may be lost from one or more cusps and this may be replaced with compressed Ivalon or silicone rubber with an Ivalon base without replacement of the total cusp (Fig. 24). Total valve replacement with three self-sealing cusps incorporated into a single unit has been accomplished experimentally and modifications of this technique will soon be used clinically (Fig. 25).

Perforation of a cusp or rupture of a cusp can be repaired under direct vision either by direct suture or by use of a cloth patch.

Aneurysms of the sinus of Valsalva are treated by excision and reconstruction of the aortic wall at the origin of the aneurysm. Ruptured aneurysm of the sinus is treated similarly with closure of the opening into the atrium or ventricle. When dissecting aneurysm is the cause of the aortic insufficiency, closure of the laceration of the inner layers of the wall can be accomplished,

Figure 22 Aortic insufficiency with deformity of noncoronary cusp. Excision of noncoronary cusp has been begun in middle figure and completed at the left.

Figure 21. Aortic insufficiency and coarctation of the aorta corrected by resection of the coarctation, insertion of aortic autograft and a plastic valvular prosthesis. Below is shown the plastic ball-valve prosthesis and the "multiple point" fixation rings.

murmurs and signs of congestive failure of varying degree and most have had angina pectoris. Patients who are in the terminal phases of their disease should not be offered operation, except as desperate risks. In this phase of the disease, their myocardium is usually irreparably damaged and cannot recover in spite of improvement in valvular function. Patients who have had acute rupture of the cusp should be treated as soon as practical by operation because of the extremely bad prognosis with medical management. Every effort should be made to screen the patients to determine those who have activity of their rheumatic process. Pa-

tients with aortic valvular lesions tolerate operation very poorly if the rheumatic process is active.

The optimal patient for operation is one who is under fifty-five years of age, with no more than moderate cardiac enlargement, but who has begun to have symptoms. Those patients who have had rapid production of severe aortic insufficiency should be offered operation very early because acute aortic insufficiency carries an extremely poor prognosis with conservative management. When multivalvular disease, such as combined mitral disease and aortic disease, is present, combined operation is advised. Similarly,

cardial and mediastinal arteries) can form additional communications with the coronary circulation and occasionally the entire cardiac blood supply may be derived from extracoronary sources.

Surgical efforts to correct the effects of coronary artery disease have taken several forms. These have included attempts to (1) develop collaterals by vascular grafts or by pericardial adhesions to the myocardium; (2) stimulate natural anastomotic channels; (3) decrease the incidence of ventricular fibrillation by nerve section; (4) increase the blood myocardial contact time by obstruction of the venous outflow tract; (5) reverse the venous circulation with arterialized blood; (6) direct removal of obstructive lesions in the coronary arteries.

At the present time several operations are in widespread use. The simple procedures have had wider application since they have lower operative risk. These include ligation of the internal mammary artery distal to its pericardiophrenic branch, and simple pericardial poudrage with talc or asbestos. Neither of these procedures has been shown to be unequivocally helpful. Both procedures, however, appear to have features which recommend them for selected cases.

Many different surgical methods have been tried to produce vascular adhesions between the pericardium and the myocardium in order to increase the flow of blood to the heart muscle. The epicardium has been shown experimentally to be a barrier for the ingrowth of blood vessels between these two structures. Most observers now believe that it is necessary to remove the epicardial barrier by physical or chemical means to secure adequate development of vascular communications. Abrasion or epicardiolysis also develops communications between the right and left coronaries to obtain a more equal distribution of the blood flow.

Poudrage procedures combined with the epicardiolysis utilize talc or asbestos to stimulate the development of vascular communications. The combination of poudrage, epicardiolysis and ligation of the great cardiac vein, or partial ligation of the coronary sinus, is a single procedure which is frequently advocated.

Reversal of circulation by anastomosis of a systemic artery to the coronary sinus has been used, combined with partial ligation of the coronary sinus distal to the point of anastomosis. This procedure has been associated with considerable operative risk and is not widely used.

Resection of the anterior plexus has been shown to decrease the incidence of ventricular fibrillation following experimental ligation of the circumflex coronary artery or the left anterior descending coronary artery. There is considerable evidence to show that ventricular fibrillation does not occur purely as a result of cardiac ischemia and that neurogenic impulses, or currents of injury in the myocardium mediated through the anterior cardiac plexus, play a role in the development of fibrillation.

Implantation of the isolated internal mammary artery into the myocardium, leaving two to four of its terminal branches unligated, has also been advocated as a method of increasing the blood supply to the myocardium. It has been shown that such implants are patent after prolonged periods and that anastomoses develop between the implant and the branches of the coronary arteries. The results of this procedure combined with epicardiolysis of the heart and sometimes with ligation of the great cardiac vein have been promising.

The success which has been obtained in the treatment of obstruction of peripheral arteries by endarterectomy has led to the application of this technique to the coronary vessels. When a localized obstruction exists, this may be removed along with the thickened intima of the vessel. Localization of the point of obstruction is obtained by means of retrograde aortography and filling of the coronary arteries through the aortic root. The injection of small amounts of contrast material following the termination of

exposures. The use of an image amplifier permits the following of the contrast medium through the coronary circuit. Some workers have employed momentary cardiac asystole induced by the injection of acetylcholine, making the injection into the aortic root during the period of asystole. The results of coronary endarterectomy have been encouraging, but it is still too early to evaluate them.

Patients who are most suitable for operation are those who manifest severe angina pectoris which is not controllable by medical means and those patients in the younger age groups in whom the prognosis is serious. These indications will gradually be extended as the benefit of operation is more fully demonstrated. An increasing number of patients previously incapacitated by coronary

Figure 23 Replacement of a single disease-involved cusp

Figure 24 Addition of substance to a scarred leaflet. This addition to the valve permits the leaflets to again form a seal.

the valvular lesion corrected and the aortic root reconstructed or replaced.

When the indirect method for the correction of aortic insufficiency is used and the plastic valve is placed in the distal arch, the flow from the upper extremities remains regurgitant. In spite of this, marked improvement has been manifest in essentially all of the patients who have had successful

Figure 25 Cusp-type valve for replacement of aortic valve

operations of this type. When successful repair can be accomplished by a direct operation, blood pressures return to normal in all extremities. A large number of patients now have had direct repair. The risk of direct operation is greater than with the previous type but is steadily decreasing. It is now possible to repair or replace the diseased aortic valve by direct means in almost all cases. The results of this type of operation are excellent with restoration of essentially normal dynamics. Operation is advised early and in these cases direct reconstruction of the valve can be accomplished with great safety.

CORONARY ARTERY DISEASE

Obstructive disease of the coronary arteries, with the resultant decrease in myocardial blood flow, is one of the principal causes of death. Coronary occlusion causes death by one of the following mechanisms: congestive failure, ventricular fibrillation, cardiac aneurysm, perforation of the interventricular septum and rupture of a papillary muscle or chorda tendina.

Anastomoses between the right and left coronary arteries are present to a varying degree in different individuals. With the development of obstruction to a coronary artery, the collateral channels between the right and left coronary vessels may increase. Extracoronary collaterals (bronchial, peri-

deceleration. Penetrating wounds may also give rise to aneurysm but more commonly give rise to pulsating hematoma or arteriovenous fistula. Those associated with non-penetrating injuries usually occur just distal to the left subclavian artery and tend to be moderate in size.

Mycotic aneurysms associated with infectious processes are seen throughout the ascending portion of the aorta in the transverse arch. They are occasionally seen in major branches. Following septic embolism, they may be found in any arterial vessel.

Dissecting aneurysm is believed to be associated with medial cystic necrosis of the aortic wall. A dissecting aneurysm should be distinguished from a leaking or rupturing aneurysm of other types. Dissection is associated with the establishment of a secondary lumen in the media which communicates with the true lumen through a break in the intima. As the dissection proceeds the two coats are further separated to a variable degree by the blood under systolic pressure. Re-entry of a dissection through a second opening in the intima is frequently associated with spontaneous cure. The majority of dissections begin in the ascending aortic arch. A considerable number of such dissections, however, begin at the level of the left subclavian artery. When the dissection begins very low in the ascending aorta at the level of the aortic valve, aortic insufficiency may be associated. Similarly, in this location the coronary artery may be occluded or avulsed.

Aneurysms of the aorta and its major branches are serious and progressive lesions, unless surgically treated they are almost universally fatal. The incidence of the various types of origin of aneurysm varies with the local incidence of syphilis. Prognosis in all such lesions is poor, but varies with the etiologic basis of the aneurysm. It is uncommon for a patient with aneurysm which is of sufficient size to be detected by physical examination or x-ray to survive for more than five years after its discovery. Individual cases of prolonged survival in patients with large aneurysms have been reported, but these are exceptional. Smaller aneurysms within the thorax seldom produce symptoms and are usually discovered by routine x-ray examination. Aneurysms of larger size may produce symptoms of varying degree. These are due to the encroachment of the aneurysm upon surrounding structures or distention of the aortic wall.

Principal symptoms include pain in the chest or back, cough due to bronchial or tracheal compression, fever from pulmonary infection secondary to bronchial obstruction, hemoptysis, hematemesis and dyspnea.

There may be no physical signs which are abnormal. There may be evidence of a mass in the thorax or mediastinum, atelectasis, congestive heart failure, evidence of superior or inferior vena caval obstruction, nerve root compression, peripheral embolization or evidence of a pulsating mass in the mediastinum or thorax. Murmurs or bruits may be present but are most frequently absent.

X-ray examination shows abnormal dilatation of the aortic shadow with intrinsic pulsations on fluoroscopy. In syphilitic aneurysm there is a characteristically linear calcification in the ascending arch. In the lower portion of the descending aorta the aneurysm may lie behind the cardiac shadow and oblique or lateral views may be necessary to delineate it. Angiocardiography and retrograde aortography may be helpful in delineating multiple masses and in differentiating saccular from fusiform aneurysms. Differential diagnosis of masses which lie in juxtaposition to the aorta may be difficult without angiocardiography since these masses may appear to pulsate because they transmit the aortic impulse. Technical developments have made possible the removal of essentially all aneurysms, providing there is no systemic contraindication in the form of the patient's general condition or other more serious disease. The treatment of choice is resection and replacement by a plastic cloth prosthesis. In exceptional instances, freeze-dried homografts may be preferable. The older methods which have included wiring and wrapping, sclerosing agents and electrocoagulation seldom find a place in the modern treatment of this disease.

Saccular aneurysms offer the simplest problem in treatment. These aneurysms usually have a narrow neck which opens into the aorta with an orifice of 1 to 6 cm. in diameter. After the aneurysm has been dissected from its surrounding structures a clamp can be applied across its base, including in it the normal aortic wall beyond the sac which can then be excised. The lateral opening is closed by sutures. In some cases there is such an extensive involvement of the aortic wall that it is preferable to remove the full diameter of the aorta and replace it

Figure 26 Ventricular aneurysm. The edges of the aneurysm are fibrous and strong. The sutured ventricular wall is shown after removal of the aneurysm.

disease are being returned to active useful lives by surgical treatment. The results of internal mammary artery implantation are particularly striking.

VENTRICULAR ANEURYSM

Ventricular aneurysm is a complication of coronary artery disease. In the immediate postinfarction period, the aneurysm may rupture, but after fibrosis is established rupture is rare. Congestive heart failure, however, is a common accompaniment of large aneurysms. The loss of effective contraction and the paradoxical filling of the aneurysm appear to be significant contributing features in this failure.

Surgical correction is accomplished by direct excision with total by-pass of the heart. The edges of the aneurysm as it joins the ventricular muscle are fibrous and strong. Reconstruction of the ventricle is extremely satisfactory. Clots which may be present in the aneurysmal sac can be removed with safety. Risk of operation is low.

ANEURYSMS OF THE AORTIC ARCH AND THORACIC AORTA

Aneurysms of the aortic arch are of six principal types: syphilitic, congenital, arteriosclerotic, traumatic, dissecting and mycotic. Syphilitic aneurysms are most common in the ascending aortic arch but may occur in the transverse or descending thoracic aorta. Less frequently they occur in the abdominal aorta. While these are frequently localized and saccular, they may involve the entire ascending and transverse arch in a fusiform manner. The saccular form may be large in total size and still have an opening into the aorta itself which is quite small. Others may be saccular in type but involve

a considerable portion of the aortic circumference. Fusiform aneurysms of the ascending arch frequently involve the aortic annulus and are associated with aortic insufficiency. The presence of linear calcium in the descending aorta is a frequent finding in syphilitic aortitis and may be helpful in establishing the diagnosis.

Congenital aneurysms are relatively uncommon, except in the sinus of Valsalva. Aneurysms of the sinus of Valsalva tend to elongate downward into the region of the right atrium or the right ventricle. When rupture occurs, it may be either into the right atrium or into the right ventricle or occasionally the rupture may occur into the left ventricle.

In coarctation, the aneurysms which are found in the aorta and intercostal vessels are rarely present at birth but develop later in life, although they may be apparent as early as six years. Other developmental abnormalities of the aorta may give rise to aneurysm either in youth or later. Overt or occult Marfan's syndrome and other forms of medial degeneration fall into this category.

Arteriosclerotic aneurysms may involve any portion of the thoracic aorta. These tend to be almost exclusively fusiform in character although they may be multiple and give x-ray appearance of sacculations. Arteriosclerotic aneurysms tend to involve large portions of the aorta and are associated with generalized dilatation of the aortic diameter in some individuals. Tortuosity and elongation of the aorta are sometimes confused with true aneurysm.

Traumatic aneurysms are usually associated with nonpenetrating injuries of the chest in which there is sudden and rapid

occurs, the heart beat restarts and when a satisfactory beat is obtained by-pass is discontinued.

By the use of one or a combination of these methods it is possible to resect essentially all aneurysms of the thoracic aorta and to replace them by prostheses. Aneurysms of the ascending arch, transverse arch and entire arch are still difficult problems. Aneurysms of the descending arch can be resected with a low mortality rate.

Rupture of an aneurysm is seldom immediately fatal but is an acute surgical emergency. The diagnosis of leakage or rupture is the prelude to death. In a high percentage of cases, the diagnosis can be made sufficiently early for surgical treatment to be highly effective. Hesitancy and excessive delay lead only to disaster.

Dissecting aneurysm has a more rapid course and more specific symptomatology than other types. These are frequently seen in a younger age group than are aneurysms of the arteriosclerotic or syphilitic type. If re-entry does not occur, survival is extremely rare. There is usually an adequate period between the onset of symptoms of dissection and occurrence of death for surgical therapy to be undertaken. Dissecting aneurysm sometimes presents itself with signs of obstruction of one of the major vessels of the extremities. Obstruction of the subclavian, carotid or iliac vessels may produce signs of ischemia in the area involved. As dissection proceeds it may also give rise to an abdominal mass which is pulsatile and suggestive of an abdominal aneurysm of the arteriosclerotic type. Onset of dissection is usually heralded by sudden severe pain which tends to radiate through the back, up into the neck or downward along the course of the thoracic aorta. When the abdominal aorta is also involved a secondary complaint may be pain in the abdomen or in the legs. Differences in the volume of the pulse or in the blood pressure on the right and left sides may give a clue to the proper diagnosis. X-rays of the chest may show enlargement of the aortic shadow to the right or to the left. Immediately after the onset, the aortic shadow may not be markedly abnormal, but over a period of several hours or days this may change markedly. Angiocardiography may show a double lumen or an irregular dilatation suggestive of aneurysm.

Operation is indicated as soon as the diagnosis is made. Diagnosis of dissecting aneurysm is also a surgical emergency which requires immediate preparation of the pa-

tient for operation. The usual procedure is to produce a re-entry point high in the thoracic aorta. Left thoracotomy is performed and the first portion of the descending aorta is freed from its surrounding structures. If the origin of the dissection is in the proximal aorta, no attempt is usually made to seek the point of origin. If the origin is at the level of the left subclavian artery, the aorta proximal to this point is normal; the area which includes the point of origin is freed so that a clamp can be placed proximal to it. When the descending aorta is cross-clamped, the double lumen of the dissection is visible. The blood is evacuated from both chambers and on the proximal side a segment of the inner wall is removed. This permits the entry of blood into the true aortic lumen at this point. In the distal segment, the false lumen is obliterated by suturing the intima to the media with multiple sutures. This converts the distal aorta into a single-lumen tube. The re-

Figure 29. Aneurysm of the aortic arch showing catheters inserted into cranial arteries and femoral artery to supply the brain and viscera during the period of interruption of aortic circulation.

CHAPTER 17. THE HEART AND PERICARDIUM

Figure 27 Aortic aneurysm of descending arch. Blood is supplied distal to the aortic clamps by a pump which removes oxygenated blood from the left atrium and replaces it by way of the femoral artery.

with a prosthesis. Teflon or Dacron materials of the seamless elastic type are preferred for this purpose.

Fusiform aneurysms which involve the descending aorta or traumatic aneurysms in this area are also excised and replaced with a prosthesis of the type described above. Since occlusion of the descending aorta cannot be safely maintained for more than thirty minutes without damage to the spinal cord or other peripheral viscera, cooling the body to 30°C . is used to prolong this safe period of occlusion. With the aneurysm isolated and all its branches ligated and divided, the aorta can be occluded above and below the lesion and the involved area excised. A prosthesis is then sutured to bridge the gap between the divided ends of the aorta. These two anastomoses can usually be completed within twenty minutes. When the aneurysm is very large and its resection cannot be safely accomplished without interruption of the circulation, blood may be shunted around the aneurysm to allow prolonged clamping of the aorta. Several meth-

Figure 28 Resection of a thoracic aortic aneurysm involving the left subclavian artery may be accomplished by the shunting technique. Blood is supplied to the lower thoracic aorta through a plastic or heterograft by-pass while the aorta is occluded.

ods are used to achieve this. A catheter may be placed into the left atrium where oxygenated blood can be withdrawn by gravity into a pump which then propels the blood back into the arterial system through a catheter in the femoral artery (Fig. 27). Thus withdrawal of blood from the left atrium reduces the load on the left ventricle while the aorta is clamped and at the same time supplies blood to the viscera distal to the aneurysm. An alternate procedure for the shunting of blood employs the suture of a prosthesis or graft to the side of the aorta proximal to the aneurysm and the other end to the aorta distal to the aneurysm (Fig. 28). Circulation is then maintained through this temporary shunt during the period of occlusion and restoration of the circulation. At the conclusion of the operative procedure the shunt is removed.

Aneurysms involving the transverse arch may be removed by means of a similar system, but one which includes additional shunts to supply the brain by cannulation of the head vessels during the period in which they are occluded (Fig. 29). An additional method employs total body cooling to a point of cardiac arrest. When the body temperature has reached 18°C the proximal and distal portions of the aorta are clamped, together with all of the branches. The aneurysm is resected and the prosthesis sutured in place. During this period the extracorporeal circulation is stopped. Following placement of the graft, the circulation is restored by means of the extracorporeal heart-lung and the blood is warmed to restore effective cardiac action. As warming

duce murmurs associated with other valvular lesions. Metastatic tumors may be associated with pericardial effusion and tumor cells can usually be isolated from this fluid. Myxomas of the atrium are prone to give rise to emboli. Such emboli when removed from the peripheral vessels show a gelatinous character which is quite characteristic.

Primary tumors of the heart are best approached by open direct-vision operation. With utilization of total cardiopulmonary by-pass, the involved chamber, usually the left atrium, is incised. After aspiration of the blood in the heart, the tumor is visualized and removed with a portion of the surrounding muscle. This defect is closed by direct suture. After the heart is refilled with blood it can be permitted to resume its normal function. Excision of that portion of the septum or cardiac wall to which the tumor is attached can result in complete removal. Tumors of the ventricle may be approached in a similar manner with excision of a portion of the ventricular wall. Malignant tumors of the ventricle, however, show invasion of such large muscle masses that total removal is frequently impossible. Angiocardiography and cinefluoroscopy are frequently helpful in localizing such intracardiac tumors. The prognosis after removal of benign tumors is excellent.

Figure 32. Pedunculated myxomatous tumor of the left atrium, which partly obstructed the mitral valve. This type of tumor is particularly suitable for surgical removal.

CARDIAC ARREST

Cardiac arrest is the general designation for the sudden cessation of an effective heart beat, occurring most often during anesthesia or surgical operation. This is an emergency which every physician must expect to meet and for which he must have a positive plan. It is imperative that every surgeon be fully aware of the problems of cardiac arrest and the mechanics of cardiac resuscitation. It demands immediate and definitive action to save the life of the patient. The well-prepared surgeon can expect to restore an effective beat with survival of the patient in a high percentage of cases. While acute cardiac arrest most commonly occurs in the anesthetized patient, it may also be seen in the immediate post-operative period associated with the passage of a nasopharyngeal tube, removal of the endotracheal tube or other pharyngeal or vagal stimulation.

The major factors precipitating arrest are hypoxia, hypercapnia, blood loss or anemia, overdose of anesthetic agents, cardiac diseases with conduction defects or coronary insufficiency, and vagal or glossopharyngeal stimulation.

Adequate ventilation and the prevention of the accumulation of carbon dioxide by the anesthesiologist are the most important preventive measures for this disaster. The use of an electrocardiograph monitor should be routine in all patients who are known to have serious heart disease.

The term "cardiac arrest" includes asystole, ineffective contractions and ventricular fibrillation, since all result in cessation of an effective heart beat. The differential diagnosis between these is made only after the thorax has been opened.

The diagnosis of cardiac arrest is made by the absence of the blood pressure and the absence of a palpable major peripheral pulse. If the anesthesiologist cannot obtain a blood pressure reading, the surgeon should immediately palpate the most accessible major blood vessel. If the surgeon has the abdomen open, the aorta or iliac arteries can be felt. The anesthesiologist should constantly check the patient's carotid pulse during all procedures. If this suddenly ceases to be palpable and the blood pressure cannot be obtained, the diagnosis of cardiac arrest must be presupposed. No time should be wasted in attempting to obtain an electrocardiogram, listening for a heart beat or other time-consuming procedures.

Figure 30 A dissecting aneurysm arising in the ascending aorta shows the characteristic double lumen. Transection of the aorta distal to the left subclavian artery permits the establishment of a re-entry site. The double lumen is obliterated distally by approximation of the two walls.

removal of the intima also leaves a single lumen proximally. The aorta is now reanastomosed, approximating these two layers (Fig. 30). If the aortic wall is extremely thin in its proximal segment, it may be reinforced externally with a layer of Dacron or Teflon cloth after the anastomosis has been completed and the circulation re-established. If the origin of the dissection can be found distal to the left subclavian artery, the aorta is sectioned proximal to the dissection. The distal segment is then converted to a single lumen and anastomosis of the two segments is then accomplished either directly or by interposition of a prosthesis (Fig. 31). These two procedures offer successful correction in an otherwise hopeless situation. Ideal therapy in acute or chronic dissection or when chronic dissection is associated with an aortic valvular lesion is direct reconstruction

Figure 31. Dissecting aneurysm which has arisen at the level of the left subclavian artery. The intimal tear has been excised and the distal lumen obliterated by sutures. Direct anastomosis or the interposition of a prosthesis gives complete restoration of normal flow.

of the aortic root with cardiopulmonary bypass. In such cases, false lumen is obliterated by suture of the two walls or suture of the inner and outer layers together with reapproximation. In some cases it is necessary to replace the ascending aorta with a prosthesis to properly reconstruct the vessel. This procedure has been successfully accomplished only in a few cases but would appear to offer a more logical approach to the problem.

TUMORS OF THE HEART

In 1783 de Senar stated, "the heart is an organ too noble to be attacked by a primary tumor." In spite of this, by 1945, over 300 primary cardiac tumors had been reported in the eighty years following the first report of a sarcoma of the atrium in 1865.

Primary cardiac tumors are infrequent but are found more often than ever before. The incidence has been variously estimated as from three to fifteen in 10,000 autopsies. The majority (4.1) of primary tumors are benign. The diagnosis of tumor of the heart has not been frequently made ante mortem until recently, when improved methods and increased awareness have led to more diligent efforts to localize the lesion and in some cases to treat it surgically.

The benign tumors most frequently encountered are fibroma, myxoma, lipoma and rhabdomyoma.

Myxomatous tumors occur frequently in the left atrium where they tend to be pedunculated and attached to the atrial wall or septum (Fig. 32). They may project over the mitral valve and simulate mitral stenosis or ball-valve thrombus. Prolapse of the tumor through the valve may cause acute mitral obstruction and death.

Muscle tumors may appear on the surface of the ventricle or deep within its substance.

Malignant tumors are dominantly sarcomas and include rhabdomyosarcoma, lymphosarcoma, fibrosarcoma, myxosarcoma, leiomyosarcoma and hemangioendothelioma.

Metastatic tumors of the heart are common. Malignant disease within the thorax, particularly bronchogenic carcinoma, is associated with direct or indirect invasion of the heart.

Signs and symptoms of cardiac tumors may be bizarre. These lesions often mimic mitral stenosis or constrictive pericarditis or pericardial effusion. They sometimes pro-

the chest in anticipation of cardiac arrest and with continuous monitoring of the electrocardiogram or an oscilloscope, electric shocks of sufficient intensity to elicit an effective cardiac contraction can be immediately instituted if standstill occurs. When ventricular fibrillation supervenes under these controlled conditions, external defibrillation may be attempted, using a shock of 700 or more volts, applied by means of the external electrodes. If these measures fail to give an immediate response in the production of an effective sustained cardiac beat, the chest must be immediately opened and the procedures previously outlined instituted.

Every operating suite should be equipped with an emergency cardiac resuscitation tray which is kept sterile at all times. The necessary drugs—epinephrine, procaine or Xylocaine, calcium chloride, digitalis, quinidine and Pronestyl—should be in a standard location in every operating room.

Following restoration of the effective cardiac beat, catheter drainage of the pleural space should be routine. The use of antibiotics intrapleurally and intramuscularly is to prevent sequelae of contamination of the pleura and pericardium. Infection of the chest or pericardium even when this procedure is done without the usual aseptic precautions is rare.

The failure to recognize cardiac arrest immediately, or hesitation in undertaking definitive action to secure cardiac massage within the first five minutes, usually results in failure in the attempt of resuscitation. If the delay has been excessive, it is sometimes possible to resuscitate the heart, but irreversible brain damage has occurred. This results either in brain stem damage with failure to resume respiration or in the loss of the higher cortical functions. Successful restoration of the heart beat should be possible in approximately 70 per cent of the patients with cardiac arrest

The left side of the chest is exposed as rapidly as possible. All anesthetic drugs are discontinued and the patient is ventilated by positive pressure with oxygen. A left antero-lateral incision should be made over the precordium beneath the breast. No time should be wasted in preparing the field, putting on gloves or counting ribs. The chest is opened through an intercostal space and immediate compression of the heart is begun through the intact pericardium. The heart is rhythmically compressed with the hand in such a fashion that the blood is forced from the apex to the base of the heart. If a spontaneous beat is not obtained after several such compressions, the pericardium is immediately opened anterior to the phrenic nerve and compression continued. Inspection of the heart will reveal whether the heart is at standstill or in ventricular fibrillation. Bimanual compression may be necessary if the heart is large or if it is atonic. With manual compression of the heart, the peripheral pulses should become palpable. Unless a pulse and blood pressure are obtainable, the compression is ineffective. Asystole and ventricular fibrillation differ in the details of management in the later phases, but in both instances the initial therapy is the same—the rapid establishment of effective cardiac compression and adequate ventilation of the lungs.

When the heart is found to be in asystole, it may resume a good beat with the first few compressions of the heart. If it does not, the rhythmic compression is continued. When the heart begins to recover, it becomes firmer and a few spontaneous beats are noted and gradually the contractions become stronger. If no improvement is noted, 5 cc. of a 10 per cent solution of calcium chloride are administered into the left atrium. The assistant compresses the aorta in its descending portion to obtain more effective circulation to the brain. The head of the patient is tilted downward. With further massage being maintained continuously at a rate of fifty to seventy per minute, spontaneous beats may occur. If the heart remains in standstill or is inefficient in its contractions, 1 cc. of 1:10,000 solution of epinephrine may be injected into the left atrium. Continuing cardiac massage and the cautious administration of calcium chloride and epinephrine in increasing doses will usually restore an effective beat. Epinephrine should be used cautiously because of the danger of precipitating ventricular fibrillation in an anoxic heart and it should be

given only when the color of the heart can be maintained well by massage.

If on inspection the heart is found to be fibrillating, the initial procedure is the same as for cardiac arrest, that is, immediate rhythmic myocardial compressions. Injection of 5 to 10 cc. of a 1 per cent solution of procaine hydrochloride into the left atrial appendage frequently will cause a restoration of a normal beat in patients who have a coarse type of ventricular fibrillation. Aortic compression and continuous massage are used as they are in patients having cardiac arrest. Block of the sinoatrial node by injection of 5 cc. of 1 per cent solution of procaine or Xylocaine may also help restore a normal rhythm.

Electric shock is frequently necessary for the defibrillation of the heart. An alternating current of 250 volts at 2.5 amperes for one-twentieth to one-tenth of a second is applied to the heart by means of electrodes which are placed on either side of the heart. The electrodes are wrapped in gauze which is soaked in saline solution. It is important that the electrodes be in firm contact with the surface of the heart and that they are not touching each other. The application of shock will usually result in cardiac standstill. The heart may then resume an effective contraction or it may remain in asystole. With compression and the cautious use of calcium chloride and epinephrine, restoration of the beat may then be accomplished.

The use of molar sodium lactate may be helpful in the defibrillation of hearts which are refractory. In patients who are hypothermic, injection of tetraethylammonium chloride into the clamped aortic root may also make possible the restoration of normal rhythm, either spontaneously or when combined with electric shock. Injection of small graduated doses of potassium citrate into the aortic root also may make possible the conversion of fibrillation which does not respond to the usual methods.

Following restoration of a normal beat, it may be necessary in some cases to digitalize the patient rapidly. If ventricular fibrillation has been present, the use of quinidine sulfate may also help prevent a recurrence.

Outside the operating room, the external pacemaker and defibrillator may be used to meet other emergency situations, particularly those which can be anticipated, such as in patients with Stokes-Adams attacks or ventricular tachycardia. The electrodes of the external pacemaker may be placed on

THE ABDOMINAL WALL AND PERITONEUM

By WALTER C. MacKENZIE, M.D.,
and ROBERT A. MACBETH, M.D.

WALTER CAMPBELL MacKENZIE was born in Nova Scotia, the only son of Canadian-Scottish parents and the grandson of a sea captain. He is the Professor of Surgery and Director of the Department of Surgery at the University of Alberta. His college and medical education were received at Dalhousie University in Halifax. He was a Fellow in Surgery at the Mayo Foundation and Clinic.

He served his country as surgical consultant to the Royal Canadian Navy and has played an important role in medical education and research in Canada.

ROBERT ALEXANDER MACBETH, born in Edmonton, the son of a doctor, was educated at the University of Alberta. Trained in surgery at McGill University, he has been a research Fellow of the National Research Council and a teaching Fellow in Anatomy. With the approach of a perfectionist, he has a great interest in medical education, research and medical history. He is an Associate Professor of Surgery at the University of Alberta.

INTRODUCTION

A painstaking examination of the abdomen is one of the most rewarding diagnostic procedures available to the physician. The student must develop an ability to appreciate even minor variations from normal while conducting this examination. To do this, he must avail himself of every opportunity during his training to examine the abdomens of normal individuals, of patients presenting

with abdominal complaints and of postoperative patients.

The physical findings elicited by examination of the abdomen, together with an appreciation of the physiologic mechanisms involved, are the key to the diagnosis of numerous pathologic conditions of the abdominal wall and more particularly of the peritoneal cavity. In an acute disease process, physical examination is most rewarding

Figure 4. Diagrammatic cross section of umbilical cord of 3.5-mm human embryo. M, omphalomesenteric duct.

embryo stage can probably be best appreciated by reference to Figure 4 which is a cross section of the cord of the embryo in Figure 3 at Y. The patent omphalomesenteric duct (M), with its accompanying artery and vein on its surface, lies in the extra-coelom (shaded) and occupies the superior portion of the cord. Inferior to it, embedded in mesenchyme, are respectively the umbilical vein, the paired umbilical arteries and the allantois. The umbilical vein divides, just before entering the embryo, into right and left branches which pass cephalad to unite with the hepatic circulation.

Figure 5 represents a diagrammatic sagittal view of a 5.2-cm. (approximately ten-week) embryo. The left umbilical vein is now shown superiorly in the cord as it courses towards the porta hepatis. The right umbilical vein disappears before the em-

bryo is 10 mm. long. The left vein remains patent until shortly after birth, at which time it becomes occluded and forms the ligamentum teres of the liver. The paired umbilical arteries are seen inferiorly, just above and on either side of the allantois. On entering the abdomen they pass inferiorly on the deep surface of the anterior abdominal wall on either side of the bladder to join their parent trunk, the aorta. After birth the umbilical arteries become occluded as far proximal as that portion which becomes the internal iliac artery. The fibrous cords representing the remains of the impervious portion are referred to as the lateral umbilical ligaments in the adult.

Considerable liberty has been taken in this diagram in reference to the omphalomesenteric duct. Normally this duct disappears when the embryo is between 4 and 12 mm. in length, though its vessels persist long after this. At the age indicated, the bowel has already entered the extraembryonic coelom, undergone its rotation and recently re-entered the intraembryonic coelom (peritoneal cavity) and normally no vestige of the duct remains. It is depicted in Figure 5 as a patent tube arising from the terminal small bowel, extending to the umbilicus and passing toward the vestigial yolk sac in the extraembryonic coelom. This has been done so that its congenital malformation may be more easily understood.

The allantois, as shown in Figure 5, has differentiated in its most caudal portion into the bladder. In the well-differentiated embryo, its intra-abdominal portion, extending from the apex of the bladder to the umbilicus, is referred to as the urachus. Even in normal embryos the obliteration of the allantois and the urachus is an irregular phenomenon and sections at a wide variety of ages may still demonstrate patent segments.

THE ABDOMINAL WALL

Little has been added to our knowledge of the embryology of the abdominal wall since the original researches of Bardeen and Lewis, reported in 1901.

The muscles of the abdominal wall are segmental in origin, arising from the lower thoracic and upper lumbar somites. They arise by differentiation of cells of the myotome (muscle plate) which multiply and, in the case of the anterolateral abdominal muscles, migrate into the somatopleure. Here the muscle fibers take up a longi-

Figure 5. Diagrammatic sagittal section of 5.2-cm. (approximately ten-week) human embryo.

and yields far more information than all laboratory investigations.

Examination of the abdominal wall is of the utmost importance in initially establishing a diagnosis, and repeated examination of the abdomen enables the physician to follow the course of the pathologic process. It should be emphasized that the pathology of disease is a continuing process and that the clinical findings elicited on abdominal examination vary with the stage of the process present in the abdominal wall or peritoneal cavity.

THE ABDOMINAL WALL

EMBRYOLOGY

THE UMBILICAL REGION

The embryology of the umbilical region has been beautifully illustrated by Brodel and described by Cullen in the latter's classic book on the umbilicus and its diseases. Figures 1 to 5 illustrate diagrammatically the essential features in this process.

Figure 1 Diagrammatic representation of 0.7-mm human embryo. A, allantois; V, vascular pedicle

Figure 1 represents a human embryo 0.7 mm. long. As can be seen, the embryo proper is capped dorsally by its amniotic cavity while it sits ventrally on its relatively large yolk sac. This entire structure is attached to the chorion and thence to the uterine wall by its broad body stalk. The body stalk is seen to contain the fetal vascular pedicle (V) made up of the paired umbilical arteries and umbilical vein and, in addition, the allantois (A) which is a diverticulum of the yolk sac.

By the time the embryo reaches 1.7 mm. long (Fig. 2) its cephalic and caudal extremities have curled ventrally, pinching off the most dorsal portion of the yolk sac which now takes a form indicative of its future development into the gastrointestinal

Figure 2. Diagrammatic representation of 1.7-mm. human embryo. A, allantois; V, vascular pedicle

tract. Note how the allantois (A) arises from that portion of the yolk sac which is taken into the embryo, so that one may now refer to this structure as arising from the primitive hindgut. It is of importance, for understanding of future events, to note at this point the depression which is evident at the neck of the yolk sac (X) and which, as a result of further development, is to contribute the coelom.

In the 3.5-mm. embryo (Fig. 3) a stage has been reached at which one may describe an umbilical cord. Enlargement of the amniotic cavity has now compressed the elongated body stalk and the elongated yolk sac stalk into a short compact structure, the anlage of the umbilical cord. The yolk sac stalk may now properly be referred to as the omphalomesenteric (vitelline) duct (M) as it lies free in the extraembryonic coelom, or exocoelom.

The structures in the cord at the 3.5-mm

curve, commonly referred to as the linea semilunaris of Spiegel. It is to be noted that in the upper abdomen, muscle fibers of the transversus are found medial to the lateral border of the rectus, where they contribute to the posterior rectus sheath.

The rectus sheath itself requires little comment. The formation of the sheath superior to the linea semicircularis of Douglas is depicted diagrammatically in the left-hand portion of Figure 6. It may be seen that the aponeurosis of internal oblique splits into two lamellae which enclose respectively the anterior and posterior surfaces of the rectus and are joined, in the former instance, by the aponeurosis of external oblique and, in the latter, by the transversus abdominis or its aponeurosis. A feature of some importance surgically is the fact that the aponeurosis of external oblique fuses with the anterior rectus sheath 2 to 3 cm. medial to the lateral margin of the rectus. This fusion allows incision of the deeper of the two leaves of the anterior sheath without disruption of the entire sheath when advancement of portions of the aponeurosis is used in herniorrhaphy. Below the linea semicircularis, which is usually situated about midway between the symphysis pubis and the navel, the aponeuroses of all three interolateral muscles pass anterior to the rectus muscle with the result that no posterior sheath exists and the rectus lies on the transversalis fascia. The decussation of the anterior and posterior rectus sheaths in the ventral midline forms the linea alba.

The structures superficial to the myoaponeurotic layer consist of the skin, superficial fascia and deep fascia, from without in. The skin of this area requires little special comment. Cosmetic considerations are seldom of paramount importance in the placement of abdominal incisions, but where they are, the long axis of the incision should parallel the tension lines of Langer. These are illustrated in Figure 8.

The superficial fascia of the anterior abdominal wall has a characteristic feature in that the fibrous stroma which supports the fat cells is condensed, in its inferior portion, to form a rather well-defined fibrous layer. This layer replaces the soft fatty tissue in the deepest portion of the superficial fascia and is referred to as Scarpa's fascia. In children it has occasionally been mistaken by the uninitiated for the aponeurosis of the external oblique muscle during herniorrhaphy. Many surgeons repair it as a sep-

arate layer in lower abdominal wound closure.

The deep fascia of the anterior abdominal wall has no peculiar features, save that while it is readily demonstrable over the muscular portion of the external oblique, it becomes fused with and inseparable from the aponeurotic portion of this muscle.

The structures deep to the myoaponeurotic layer consist of the transversalis fascia, the extraperitoneal fat and the peritoneum, from without in. The transversalis fascia is characterized by its firm attachment medially to the posterior rectus sheath, its loose attachment to the transversus abdominis muscle and its uninterrupted continuity posteriorly with the fascia over the quadratus lumborum and psoas muscles. Superiorly, it is continuous with the fascia on the inferior surface of the diaphragm and inferiorly with that on the visceral surface of the muscle lining the pelvic cavity.

The distribution of the nerves of the abdominal wall is illustrated in Figure 9. The lower five intercostal nerves and subcostal nerve can be seen to pass downward and medially in the plane between the internal oblique and transversus muscles. They pierce the posterior leaflet of the aponeurosis of the internal oblique muscle at the lateral margin of the rectus sheath, continue their course posterior to the rectus muscle and terminate by supplying branches to this muscle and the overlying skin. The distribution of the iliohypogastric and ilioinguinal nerves from the first lumbar segment is

Figure 8. The tension lines of the skin of the ventral surface of the trunk.

Figure 6 Left half transverse section showing the structures at the level of the first lumbar segment in the adult
Right half corresponding section showing diagrammatically the structures of an embryo at three weeks

tudinal direction, extending between the septa which separate the segments. With further development, muscle fibers of adjacent segments fuse, undergo lamination into layers and finally the fibers of the various laminae modify their direction to conform with the final pattern as seen in the adult. The final step in this process is the fibrous replacement of certain areas of the muscles with formation of their respective aponeuroses. Reference to Figure 6 indicates the source of these muscle fibers

The basic vasculature of the abdominal wall, too, is derived from the segmental vessels. The arteries, for example, arise in pairs from the aorta, contribute a branch to the epaxial muscles, spine and skin of that segment and then course ventrally in the somatopleure (body wall) to anastomose with the corresponding paired ventral longitudinal vessels (superior and inferior epigastric). The venous pattern is similar, as is, in essence, the pattern of the peripheral nerves, though no ventral longitudinal nerve completes the analogy

ANATOMY

In this discussion there are certain features of the anatomy of the abdominal wall which warrant brief review

The anterior abdominal wall may be looked upon as a laminated structure, of which the middle or myoaponeurotic layer functions as the essential supporting framework. This layer is composed of the anteriorly placed rectus muscles and the laterally situated flat muscles of the abdominal wall, with their aponeuroses. The fibers of the paired recti run longitudinally from the crest of the pubis to their insertion into the

cartilages of the fifth, sixth and seventh ribs. Lateral to the recti, and forming what are commonly referred to as the muscles of the anterolateral abdominal wall, are the external oblique, internal oblique and transversus muscles, in that order, from without in. The origin of these muscles and the direction of their fibers needs no comment here, but the point at which their muscle fibers become aponeurotic is a feature of some importance, which is seldom referred to in anatomic texts in the English language. Reference to Figure 7 indicates that the line of transition from muscular to aponeurotic fibers in the case of the external oblique may be represented by a line dropped vertically from the tip of the ninth costal cartilage to join the lateral portion of a line drawn from the anterior superior iliac spine to the umbilicus. In the case of the transversus, the line of transition is indicated by a sigmoid

Figure 7. Myoaponeurotic junctions of the anterolateral abdominal muscles.

sions of the urinary tract are very common and considerable discussion centers around which of the two lesions is the primary one. Congenital malformations of the gastrointestinal tract, mainly in the form of malrotation, occur in at least 20 per cent of cases. Respiratory and urinary infections have been the most common fatal complications. Treatment consists of external support to the abdominal wall, early surgical correction of associated urinary and gastrointestinal abnormalities and general measures directed toward the maintenance of an optimal nutritional state and the prevention of complicating infections.

ABNORMALITIES IN THE REGION OF THE UMBILICUS

Omphalomesenteric Duct Anomalies (Fig. 11). While Meckel's diverticulum is by far the most common lesion in this class, occurring in some 2 to 4 per cent of persons, it is dealt with in the chapter on congenital lesions of the gastrointestinal tract.

Instances of completely patent omphalo-

mesenteric duct are extremely rare. In 1916 Cullen was able to collect only forty-eight cases. However, Gross reports eleven cases seen in as many years at the Boston Children's Hospital and reports are becoming more frequent in the literature. The diagnosis should be suspected in a newborn infant presenting with a reddish moist pouting collection of intestinal mucosa at the navel. The intestinal origin of the tissue, as opposed to the more common umbilical granulation, may be suspected by the clinical demonstration of the mucoid nature of its secretion. Intestinal mucosa may, of course, also occur at the navel in association with umbilical polyps and umbilical sinuses, but these three can usually be differentiated by judicious probing and by means of x-ray examination following Lipiodol injection of the sinus, if one exists. The diagnosis is immediately confirmed if, on crying or straining, the infant is observed to pass gas or discharge fecal material from the navel. Souitar and his associates warn against complacency in those instances in which normal gastrointestinal tract function appears to exist in the presence of a completely patent omphalomesenteric duct. At least thirty-seven cases of ileal prolapse are recorded and this may occur suddenly and rapidly endanger life. The degrees of ileal prolapse are illustrated in Figure 12. The treatment consists of complete excision of the umbilicus and the tract. The ileum is closed transversely following longitudinal excision of the tract from its wall. When the operation is

Figure 9 The anterior abdominal wall. In the right half of the figure the rectus muscle has been removed to show the structures lying on the posterior rectus sheath and the external oblique muscle has been reflected downward and a window has been opened in the internal oblique to show the intercostal neurovascular bundles.

slightly different. As illustrated, they pierce the internal oblique muscle just medial to the anterior superior spine and thus lie in the plane between the internal oblique muscle and the aponeurosis of the external oblique, in which situation they are displayed at herniorrhaphy.

The segmental arteries, the posterior intercostal and lumbar branches of the aorta, follow the distribution of the corresponding nerves and terminate in anastomoses deep to the rectus muscle with the superior and inferior epigastric arteries. In their course they anastomose with the ascending branch of the deep circumflex iliac artery deep to the internal oblique muscle. The veins of the abdominal wall course with their corresponding arteries.

The lymphatic drainage of the abdominal wall is of importance with regard to the spread of infections and malignant disease. It is illustrated diagrammatically in Figure 10. On the right hand side of the figure the superficial drainage is shown. A line drawn around the body, from just above the umbilicus to the disk between the second and third lumbar vertebrae, separates the superior from the inferior watershed. The medial portion of the superior watershed drains into the pectoral group and the lateral portion into the subcapular group of the axillary nodes. The inferior watershed, including the integumentum of the umbilicus, drains into the superficial inguinal nodes. There are no significant anastomoses between the superficial lymphatics of the left and right sides of the abdominal wall except at the umbilicus.

Figure 10. Lymphatic drainage of the abdominal wall. Right half, drainage of superficial structures. Left half, drainage of deep structures.

The lymphatic drainage of the deep structures of the abdominal wall is shown on the left half of the figure. The lymphatics are seen to course to the internal mammary, the axillary, the abdominal aortic and the deep femoral nodes from fairly well-defined areas of the wall. Again the unilaterality of the lymphatic drainage is preserved except for the area immediately around the umbilicus. The umbilical lymphatics communicate freely with channels which pass to all four drainage areas bilaterally and also, by means of lymphatics traveling along the round ligament of the liver, drainage may be to nodes in the porta hepatis.

CONGENITAL ABNORMALITIES

ABNORMALITIES OF THE MUSCLES OF THE ABDOMINAL WALL

Agensis or absence of the muscles of the abdominal wall is a rare abnormality and, even in the cases reported, extreme deficiency rather than absence would appear to be a more appropriate term. Baxter reports a ratio of about one case of agensis of the muscles of the abdominal wall to seventeen cases of the relatively more common anomaly affecting the pectoral muscle group. Silverman and Huang were able to collect only forty-eight cases which had appeared in the literature up to 1950. They note that the transversus abdominis, the portion of the rectus abdominis below the navel, the internal oblique, the external oblique and the rectus abdominis above the navel are affected in decreasing order of frequency. An interesting sex incidence is recorded in that only two of forty-five acceptable cases occurred in female children. Associated le-

should be restricted to incision, drainage and loose packing of the cavity with gauze. Frequently, as a result of the infection, the transitional epithelium of the wall of the cyst is destroyed and the simple drainage procedure results in permanent cure.

Urachal bladder diverticula are considered in connection with the urinary tract.

Vascular Anomalies. Vascular anomalies involving the omphalomesenteric vessels are rare and of little clinical significance. Aberrations in the normal fate of the umbilical vessels are apparently rare if one excludes the possibility that portal vein obstruction may be due to extension into that vessel of the obliterative process that is normally limited to the umbilical vein and ductus venosus. Anomalies of the urachal vessels are apparently of little or no clinical significance.

Somatic Anomalies. Omphalocele, umbilical hernia and extrophy of the urinary bladder are somatic anomalies which occur frequently enough to require serious consideration for surgical treatment.

Endometriosis of the umbilicus is rare. It usually presents as a small mass at the umbilicus which enlarges and becomes tender at the time of the menstrual period. External bleeding may also occur. Treatment is by simple excision. Coexistent pelvic endometriosis will require separate treatment.

INFECTIONS OF THE ABDOMINAL WALL

INFECTIONS OF THE UMBILICUS

Omphalitis of the Newborn. While this condition is much less common now than twenty-five or more years ago, it may be a serious lesion and therefore demands prompt recognition and treatment. It usually arises as a result of contamination of the cord at the time of section or during subsequent dressing of the umbilicus. The common organisms are the *Staphylococcus aureus* and the hemolytic streptococcus. The widespread lymphatic drainage and the persistence of patent vascular channels in this area account for the rapid dissemination of the infection.

Locally, the condition is manifest by redness, heat, swelling and tenderness which may spread centrifugally from the navel with alarming rapidity. Usually pus exudes from the folds of the umbilicus. Occasionally, widespread sloughing of skin occurs. Blood stream invasion may occur along the incompletely obliterated umbilical vein or umbilical arteries with signs of septicemia. Spread sometimes occurs to the adjacent peritoneum with signs of fulminating peritonitis.

Treatment of the omphalitis must be initiated promptly with antibiotics, local hot moist compresses and surgical incision of any purulent collections. The localized type of omphalitis usually responds rapidly to treatment, but once septicemia or peritonitis has occurred the outlook is grave.

Omphalitis in the Adult. Unlike neonatal omphalitis, umbilical infections in the adult tend to pursue a relatively benign and chronic course. They are commonly seen in office practice but seldom require hospital care. The one common etiologic factor in almost all cases appears to be neglect of personal hygiene in this area. Congenital aberrations in the depth and configuration of the umbilicus may contribute by making cleansing of the area difficult.

The usual complaints are of tenderness in or around the navel and the presence of a seropurulent discharge with an offensive odor. Examination reveals the base of the umbilicus thrown up into a cluster of red, moist, swollen, angry-looking folds which exude the offensive discharge. Extension into periumbilical tissues is uncommon but may occur along with inguinal adenitis.

In the acute phase omphalitis rapidly responds to warm, moist saline compresses and hydrogen peroxide instillations. Antibiotics are seldom indicated. Once the acute symptoms have subsided, the patient should be instructed to wash the umbilicus carefully while bathing and dry it with equal care afterward. Gentle cleansing with alcohol-dipped absorbent cotton on the end of an applicator is a useful means of eliminating moisture and excoriation in deep clefts.

INFECTIONS OF THE ABDOMINAL WALL

Infections of the abdominal wall proper are essentially similar to superficial infections occurring elsewhere in the body. Progressive bacterial synergistic gangrene and other relatively rare infections of this area may produce serious postoperative complications.

TRAUMA TO THE ABDOMINAL WALL

Injuries to the abdominal wall often tax the diagnostic acumen of the examiner. The major problem is to differentiate those lesions limited to the wall from those traumatic intra-abdominal lesions which may rapidly endanger life and for which immediate surgical intervention is mandatory.

Wounds of the abdominal wall, as opposed to blunt trauma where no open wound exists, may be considered under two broad

carried out before ileal prolapse with vascular embarrassment has occurred, the mortality is minimal.

Umbilical sinuses and polyps are treated by excision. Vitelline cysts are usually asymptomatic unless obstruction occurs around the congenital band which joins them to the ileum or to the navel. Small cysts situated close to the navel or within the abdominal wall, or larger cysts occurring more proximally along the duct, may be palpable. The only satisfactory treatment is excision.

Congenital bands, of either omphalomesenteric duct or vascular origin, are of importance only as an etiologic factor in intestinal obstruction. Bremer makes the interesting observation that a band derived from the obliterated omphalomesenteric artery corresponds in position to that shown for the congenital band in D of Figure 11, while that derived from the corresponding vein runs, not to the antimesenteric border of the bowel, but rather to the base of the mesentery at a more proximal level, or to the porta hepatis.

Urachal Anomalies (Fig. 13). Cullen in his book briefly presents some sixty cases of congenital completely patent urachus reported in the literature up to 1916. Gross was able to report on ten cases observed at the Boston Children's Hospital. The condition is characterized clinically by the intermittent discharge of urine from the navel, the quantity and the frequency depending on the caliber of the fistula and the presence or absence of some degree of obstruction of the lower urinary tract. A small granular tumor may mark the site of the ostium at the umbilicus or the navel may appear normal on superficial examination. No symptoms, apart from the discharge, are associated with the anomaly unless infection occurs. Surgical excision is the only satisfactory treatment, but this should be performed only after the patency of the urethra has been confirmed. The entire tract is excised and the site of attachment to the bladder is ligated and inverted with a purse-string suture. In the absence of pre-existing infection the procedure can usually be accomplished extraperitoneally with minimal risk.

In the so-called acquired type of completely patent urachus, no abnormality is apparent at birth and only at some later date does intermittent discharge of urine occur. Such cases are almost invariably associated with lower urinary obstruction which forces urine through an incompletely obliterated urachal channel. Treatment is

Figure 13 Congenital urachal anomalies

excision following correction of the obstructing lesion. The acquired type of anomaly is more common than the congenital type.

Umbilical urachal sinuses present no additional features except that the discharge is minimal and watery and is not urine. Treatment consists of surgical excision.

Urachal cysts are the most common urachal abnormality. If uninfected they are usually asymptomatic and, when small, are recognized only at surgery or autopsy as an incidental finding. Larger cysts may be apparent to the patient as a subumbilical fullness or swelling or may be discovered incidentally by the surgeon in the course of abdominal examination. Infection is common and this is the usual method of clinical presentation. The picture, then, will be one of an acute inflammation deep in the subumbilical abdominal wall. In cases in which the cyst is not infected, extraperitoneal excision is the treatment of choice and usually presents no difficulties unless the cyst is of large size. It is wise in such cases to demonstrate the cord, which almost invariably runs from the cyst to the bladder, and to deal with it as though it were patent by the method previously referred to. This precaution is also desirable in cases of umbilical urachal sinus. In the case of infected urachal cysts, excision without peritoneal contamination is virtually impossible and treatment

this finding after abdominal trauma is of extreme importance. It may arise, on the one hand, from a relatively benign injury to the abdominal wall or, on the other, from a grave intraperitoneal insult which will be rapidly fatal if surgery is withheld. It should be possible in every case to differentiate these two on a basis of complete and careful abdominal examination.

Abdominal wall rigidity as an early manifestation of purely thoracic wounds is now well recognized. Frequently the rigidity, which is usually ipsilateral but may be bilateral, is associated with subcostal tenderness of such intensity, in the early hours after injury, that one is tempted to carry out a laparotomy with a diagnosis of ruptured intra-abdominal viscus. The knowledge that this syndrome may exist, along with the absence of signs of peritoneal contamination, should enable one to avoid needless laparotomy. The abdominal findings rarely persist over forty-eight to seventy-two hours.

The converse situation is frequently observed, namely, unilateral restriction of movement of the thoracic cage and diminished air entry into the base of the lung on that side, following injury restricted to the abdominal wall. Percussion of the chest along with radiologic examination will quickly clarify the situation.

HEMATOMA OF THE RECTUS SHEATH

In recent years this uncommon condition has aroused much interest because of the fact that it may mimic acute intra-abdominal disease. It is seldom diagnosed preoperatively because it is not considered. In approximately 90 per cent of cases the hematoma is situated below the navel and it lies to the right of the midline about twice as often as it does to the left. The frequent occurrence of the hematoma below the semicircular line of Douglas, causing peritoneal irritation, is considered to account for the gastrointestinal manifestations which are often seen. It is seldom possible to demonstrate the exact site of hemorrhage, but the inferior epigastric vein is more commonly the source than the artery.

Insofar as etiology is concerned, there is general agreement that the condition is more frequent during pregnancy. Even in this group it is usually possible to elicit a history of indirect trauma or upper respiratory infection with cough as the immediate cause of the hemorrhage. Apart from pregnancy, the cases may be broadly classified into those associated with:

1. Trauma—either direct or indirect, of which the latter is far more common.
2. Infections and Debilitating Disease—in which case a severe paroxysm of coughing is often the immediate cause of the hemorrhage.
3. Degenerative Vascular Disease, Blood Dyscrasias and Abnormalities of Coagulation—which includes an increasing number of cases ascribed to anticoagulant therapy.
4. The Postoperative Patient—in whom the injudicious positioning of rectus muscle retractors or retention sutures is usually the cause.
5. Idiopathic—this latter group implies that the lesion can occur spontaneously without associated disease or injury. This appears most unlikely and it is probable that one of the above factors is present, though overlooked, in cases so classified.

The symptomatology is classical. Following trauma, which may be mild or severe, there is usually a rather sudden onset of excruciating abdominal pain. In cases in which the bleeding occurs slowly, the pain will be more gradual in onset and of less severity. It is usually localized to the site of rupture but may be generalized. Nausea and vomiting are relatively common and constipation may occur. Characteristically, after a period of increased pain, there is a gradual improvement which leaves in its wake a persistent dull ache.

Apart from the occasional patient who appears acutely ill and shocked, the significant findings are limited to the abdomen. Here one finds a hard exquisitely tender mass in one or the other rectus, which may be misinterpreted as localized muscle spasm. If one demonstrates that the mass is restricted to the confines of the rectus sheath and that tenderness and rigidity in the adjacent lateral abdominal muscles are lacking, the diagnosis is supported. Fothergill has described a sign which assists in differentiating abdominal wall masses from those arising within the peritoneal cavity. When the recti are contracted, as in attempting to sit up, a mass situated in the wall may still be felt and is fixed, while an intra-abdominal mass is no longer easily palpable. An additional late sign, which has been observed in a number of cases, is the appearance of ecchymosis about the umbilicus which may extend down into the scrotum or perineum.

The hematoma is usually accompanied by a mild elevation of temperature and pulse

headings By convention, involvement of the peritoneum is considered the dividing line between these two types of injury

Nonpenetrating wounds involve only the abdominal wall proper Like wounds elsewhere, they show all gradations from clean incised wounds to gaping defects with much loss of tissue. In depth, they vary from disruption of skin continuity alone to involvement of all layers including muscle. Apart from those wounds associated with considerable loss of tissue, where some type of plastic procedure may be necessary, the treatment of nonpenetrating abdominal wounds is similar to that of wounds elsewhere in the body and follows the principles laid down for the surgical care of soft tissues.

Penetrating wounds constitute an entirely different problem. Such injuries occur mainly as a result of gunshot and stab wounds, although almost every conceivable foreign body has at some time been recorded as the traumatizing agent Not all gunshot and stab wounds are, of course, penetrating. Loria, reviewing a series of 4341 such cases encountered at the New Orleans Charity Hospital, reports approximately two-thirds to be penetrating and one-third to be nonpenetrating There is rather universal agreement, however, that unless such a puncture type of wound is very obviously nonpenetrating it should receive prompt surgical attention. In penetrating trauma the injury to the abdominal wall is usually of minor importance and the demonstration and correction of the intra-abdominal component are the prime considerations

Firstly, it is usually unwise to attempt to probe the wound tract If the depth of the wound cannot be determined it is far better, as pointed out by Gaston and Mulholland, to examine the parietal peritoneum through a planned, initially small incision adjacent to the wound This incision may be closed, if the peritoneum is intact, or rapidly extended to give wide access to the abdominal cavity, if peritoneal penetration has occurred Secondly, where wounds of entrance and exit exist, the incision is selected which will give the best access to the anticipated intraperitoneal damage and no attempt should be made to incorporate such wounds into the incision. Thirdly, on completion of the intraperitoneal procedure and after consideration of the condition of the patient, the puncture wounds may be either simply cleansed and dressed or excised and closed,

depending on their character and degree of contamination.

Blunt trauma to the abdomen is linked in the minds of surgeons with the multitude of puzzling intra-abdominal lesions which so frequently accompany this form of injury and little attention is usually given to isolated abdominal wall lesions which may occur Contusion and hematomas of the subcutaneous tissue and muscle layers are common but seldom are of serious significance or require more than symptomatic treatment. Their main interest to us stems from the pain and muscle spasm which they produce and which must be differentiated from similar symptoms and signs produced reflexly by intra-abdominal injury Occasionally, as a result of blunt trauma, subcutaneous rupture of the muscles of the abdominal wall occurs without disruption of the skin, as recorded by Jamieson

SPASM OF THE MUSCLES OF THE ABDOMINAL WALL

Spasm of muscles of the abdominal wall, particularly the rectus abdominis, is a common finding on examination A relatively simple classification of the causes of abdominal wall spasm would include:

- I. Central or Cerebral Origin
 - a. Organic, as seen in spastic paraplegia.
 - b. Psychogenic, as seen in the nervous patient, the patient anticipating some painful experience or in psychopathic drug addiction.
- II. Spinal Cord Origin, as seen in those diseases characterized by irritation of spinal cord neurons, as for example tabes dorsalis.
- III. Thoracic Nerve Trunk Origin, as seen in pleurisy, infections of the chest wall, chest and spinal column injury, epidemic pleurodynia and severe alcoholic neuritis
- IV. Reflex Origin, as seen when the peritoneum is irritated by infection, blood or foreign material or when juxtapertoneal organs are the origin of extremely painful stimuli, as in renal colic
- V. Local Origin, as seen in local trauma to, or infection of, the abdominal wall

While peritonitis, in its broadest sense, is by far the most common cause of true abdominal wall rigidity, the interpretation of

lomen. Less commonly, a vague feeling of pressure on the bladder or bizarre abdominal pains may cause the patient to seek advice. On examination, a mass is usually palpated deep to the skin and unattached to it. Characteristically it is firm, smooth and discrete. Bouchacourt's sign, which is similar to that of Fothergill but applies to intramural masses situated anywhere in the anterior abdominal wall, is helpful in localizing the mass to the muscular layer of the abdominal wall. The rectus abdominis is the muscle most commonly affected, but the infiltrative nature of the tumor frequently results in multiple muscle involvement.

The gross pathologic features of the tumor are its denseness and hardness, its glistening white or pinkish color and its apparent infiltrative character. Microscopically, it varies from an acellular fibroma to a low-grade cellular fibrosarcoma and the inclusion at its periphery of engulfed and sequestered degenerating muscle fibers is characteristic.

Desmoid tumors are clinically benign and metastases do not occur. Local recurrence is the rule, unless excision has been complete. Treatment is by wide surgical resection which, because of the large size of some of these tumors, often results in defects which require plastic procedures for closure. The place of radiation therapy in the management of these tumors is controversial and no opinion as to its value is possible at this time.

MALIGNANT TUMORS

The malignant tumors constituted 38 per cent of all neoplasms and, of this group, it is interesting to note that secondary malignant tumors were as common as primary malignant growths. This is in marked contrast to other soft tissue areas where secondary deposits are extremely rare. The remainder of this group consisted of malignant lymphomas. These latter cases were instances in which the initial presentation of the disease took the form of an abdominal wall mass.

Primary Malignant Tumors. Of this group approximately one-half were sarcomas. The more common sarcomas, in order of frequency, were: neurogenic sarcoma, spindle cell sarcoma, synovium and rhabdomyosarcoma. The carcinomas encountered were mainly epidermoid in type with occasional basal cell lesions and very rarely an adenocarcinoma. There were eight melanomas in the entire series.

Most of the sarcomas arose from the

deeper layers of the wall and not infrequently gave rise to blood-borne metastases, though lymph node involvement did not occur. As a group these sarcomas tend to be radioresistant and the treatment, if treatment is possible, consists of wide excision of the full thickness of the abdominal wall, including the peritoneum. Synovium and rhabdomyosarcomas appear to have a particularly unfavorable prognosis.

Carcinoma of the skin of the abdominal wall is relatively uncommon, as compared with its occurrence elsewhere in the body. It does, however, present some interesting and rather unusual features when it occurs in this situation. In twelve of the seventeen cases in the series referred to, epidermoid carcinoma arose in an area of pre-existing tissue abnormality such as an abdominal scar, an abdominal sinus or an area of radiation dermatitis. Epidermoid carcinoma, arising in normal skin, has a relatively good prognosis following total surgical removal. Superficial lymphatics are scarce in the abdominal wall and lymph node metastases are unusual. Epidermoid carcinoma arising in laparotomy scars and postoperative draining sinuses is a clinical entity with an extremely grave prognosis, for while lymph node metastases are rare, early extensive involvement of the peritoneum is common.

Melanomas appear to be relatively uncommon in the abdominal wall. Stewart, Hay and Varco report an incidence of 3.26 per cent in a group of ninety-two cases, while Pack and Ehrlich could report only eight cases. These lesions appear to have a predilection for the area about the umbilicus which, as we have seen in connection with the anatomy of this region, is a most undesirable situation from the standpoint of facility of lymphatic and venous spread. Melanoma carries with it a grave prognosis and since these lesions are rarely radiosensitive, radical surgical excision is the only available treatment which offers any hope of eradication of the disease. Wide local excision of the lesion is mandatory and this, at the umbilicus, includes ample excision of the full thickness of the abdominal wall and the round ligament of the liver. Block dissection of lymphatic glands in areas of apparent spread should be carried out. If the lesion is situated in a quadrant of the abdomen where its lymphatic drainage can be predicted with assurance, then block dissection of the regional lymphatics should be carried out even in the absence of clinically demonstrable metastases. The principle of

and moderate polymorphonuclear leukocytosis is common, further simulating acute intra-abdominal disease.

The natural history of the disease is usually one of spontaneous recovery with cessation of pain after a few days and gradual disappearance of the mass in the course of three to four weeks. Occasionally the hematoma becomes infected and forms an abscess or persists and calcifies to give rise to continuing pain. Schafer in his collected series of 101 cases makes it clear that the condition is not to be considered innocuous for he reports nine deaths, seven directly attributable to the hemorrhage.

Some surgeons feel that the safest and surest treatment is to confirm the diagnosis by means of a short paramedian incision, evacuate the clot and ligate the epigastric artery and vein above and below the assumed point of hemorrhage. It is our belief that most of these cases can be successfully managed conservatively. It should be pointed out that some patients will be operated upon in error with a preoperative diagnosis of appendicitis or some other intra-abdominal lesion. In this group surgical control of the hemorrhage is readily carried out.

TUMORS OF THE ABDOMINAL WALL

Pack and Ehrlich, in a report dealing with 391 cases which they observed at the Memorial Hospital in New York, draw attention to the fact that tumors in this region frequently present unique problems which warrant their study as an isolated group.

BENIGN TUMORS

Benign tumors constituted 62 per cent of all neoplasms and 80 per cent of the primary neoplasms. In order of frequency, the more common types of benign tumors encountered were: lipomas, neuronevi, hemangiomas, epithelial papillomas, fibromas, neurofibromas, keratoses and desmoid tumors. Lipomas, constituting 20 per cent of the benign neoplasms, were the most common tumor encountered in the entire series. The treatment of these lesions is similar to that recommended in other situations and presents no special problem. Lipomas, papillomas, fibromas and keratoses are treated by simple excision. In the case of hemangiomas, we also favor surgical excision when the lesion occurs in the abdominal wall since cure is rapidly achieved and the resulting scar is of little consequence. Others favor carbon dioxide snow and radiation therapy for superficial lesions. It is interesting to note

that Scott, in a review of hemangiomas of skeletal muscle, found 4.3 per cent in the muscles of the abdominal wall.

Neurofibromas of the solitary type are easily excised surgically, but in over half of the cases in which this lesion presented in the abdominal wall it took the form of the plexiform von Recklinghausen type. This lesion, with its known predisposition to malignant transformation, was often extensive and invasive and required wide excision, sometimes in stages.

Nevi of the abdominal wall must be treated with considerable respect. Eighteen per cent of the pigmented nevi in this series turned out to be malignant melanomas and seven out of eight melanomas encountered gave a history of chronic irritation of a pre-existing mole. It is obvious that any such lesion should be widely excised surgically, especially if it presents in an area in which irritation from a belt, girdle or other clothing occurs.

DESMOID TUMORS

Desmoid tumors are essentially hard fibromas arising from the musculoaponeurotic structures of the anterior abdominal wall. Some include tumors of sunilar character occurring in other skeletal muscle groups under the same heading. Unlike the usual fibroma, which tends to be situated subcutaneously, these tumors, arising from the more deeply placed fascial and aponeurotic layers, are not encapsulated. They are characteristically infiltrative and tend to attain large size. The etiology of these lesions has never been satisfactorily explained. The preponderance in the female (80 to 90 per cent) and the frequent appearance of the tumor within a year following parturition have led to the suggestion that stretching of and trauma to the abdominal wall during pregnancy, or some endocrine factor associated with gestation, may be the important etiologic factor. However, the occurrence of this type of tumor in a significant number of male and nulliparous female patients, as observed in the series of Pearman and Mayo, would tend to minimize the etiologic significance of pregnancy. A definite history of antecedent abdominal trauma is also rare, though in some series the occurrence of desmoid tumors in previous laparotomy scars is too frequent to be dismissed as incidental.

Clinically, the patient usually presents complaining of the presence of an abdominal mass or a sensation of weight in the ab-

Figure 16. Cross section through that level of the gut destined to become the second part of the duodenum. There is no ventral mesentery at this level and the peritoneal cavity is a continuous space. The hepatic diverticulum (H) arises by evagination ventrally and will give rise to the ventral contribution to the pancreas and to the biliary tree and liver. The pancreatic diverticulum (P) arises by dorsal evagination and forms the major portion of the pancreas.

to two evaginations (Fig. 16). Into the ventral mesentery grows the hepatic diverticulum, from which branches the accessory pancreas. Into the dorsal mesentery grows the diverticulum which is to become the main pancreas. In the dorsal mesogastrium, the spleen develops in relation to blood vessels (and not lymphatics) and then bulges into the left leaf of the mesentery (Fig. 17).

The mesenteries of the foregut shift their attachments as the stomach rotates 90 degrees on a long axis and as overgrowth takes

Figure 17. Cross section somewhat cranial to that

the ventral mesogastrium and septum transversum to give rise to the liver. The pancreatic diverticulum will extend cranially in the dorsal mesogastrium and come to lie dorsal to the spleen. Subsequent rotation of the stomach with its mesenteries will cause these structures to lie to the right (liver) and left (spleen and pancreas) of the stomach.

Figure 18. Cross section through a four-month fetus at approximately the level shown in Figure 17. The liver and pancreas have grown cranially from their points of origin shown in Figure 16. Rotation has converted the right half of the peritoneal cavity shown in Figure 17 into the lesser sac. It can be seen that fundamentally the spleen and pancreas lie in the dorsal mesentery of the stomach.

place on the greater curvature side (Fig. 18). The ventral mesentery, bearing the hepatic diverticulum (common bile duct), shifts to the right and cranially to become the lesser omentum.

The rotation of the foregut is accompanied by a shift in the attachments of its dorsal mesentery, bearing the spleen and a major portion of the pancreas. The dorsal mesogastrium balloons to the left and caudally. The cranial portion adheres to the posterior wall of the peritoneal cavity and the adjacent layers of mesogastrium and parietal peritoneum disappear. Thus, the pancreas takes its permanent retroperitoneal position and the cranial portion of the dorsal mesogastrium takes its attachment from the left posterior body wall in the form of the gastrolenal and lienorenal ligaments, which are really a single mesentery with the spleen protruding from the left anterior leaf.

The caudal portion of the dorsal mesogastrium overlaps the transverse mesocolon and fuses with it, so that the mesogastrium appears to take origin from the transverse colon itself. Considerable further overgrowth of the dorsal mesogastrium between the greater curvature of the stomach and transverse colon produces an apron of redundant tissue which descends into the lower abdomen and then doubles back on itself to form the greater omentum (Fig. 19).

The "physiologic herniation of the midgut" and the process of intestinal rotation should be reviewed frequently, because an appreciation of these processes is necessary in order to understand the retroperitoneal position of the duodenum, the obliquity of

excision of the primary lesion with dissection of the regional lymphatic nodes in continuity can frequently be effectively employed in the case of the abdominal wall.

Secondary Malignant Tumors. Reference has already been made to the relatively frequent occurrence of secondary malignant spread to the abdominal wall in contrast to the infrequent occurrence of such spread to other soft tissue areas. The source of the metastatic deposit is most commonly a carcinoma (85 per cent) and in the series of Pack and Ehrlich the common sources in order of frequency were the ovary, stomach, uterus, bronchus, kidney, breast and sigmoid colon. Metastatic carcinoma of the abdominal wall most commonly occurs in the region of the umbilicus. Cullen has collected a series of such cases which would implicate the stomach rather than the ovary as the most common source. An interesting story is often told in this connection. Sister Joseph, who was in charge of St. Mary's Hospital in Rochester, and who functioned as the able assistant to Dr. William Mayo in the early days of the Mayo Clinic, is said to have initially drawn to Dr. Mayo's attention her observation that, in the preparation of gastric cases for surgery, she occasionally noted a very firm mass at the patient's umbilicus. She further observed that patients so afflicted did particularly poorly following operation. This astute observation is often acknowledged by applying the term "Sister Joseph's sign" to the demonstration of umbilical metastatic deposits in cases of intra-abdominal malignancy.

The presence of secondary malignant deposits in the abdominal wall, with one notable exception, is a sign of advanced disease and inoperability. The one exception is the implantation carcinoma which is occasionally seen in the scars of operations carried out for malignant disease. These lesions, surprisingly, do not tend to invade the peritoneal cavity and while lymph node metastases may occur, wide surgical excision of the implanted lesion, along with block dissection of involved nodes, may be rewarded by long-term survival.

THE PERITONEUM EMBRYOLOGY*

The primitive coelom is partially divided by the septum transversum, or future dia-

* Strict regard for chronology has been avoided in this description in order that the development of each structure might be treated as a unit.

Figure 14. Parasagittal section of an embryo at four weeks. The thick septum transversum divides the coelom into the pericardial cavity (A) and the peritoneal cavity (B). The two cavities communicate over the dorsal aspect of the septum transversum by means of the pleural canals.

phragm, into a pericardial cavity and a peritoneal cavity in the fourth week of intrauterine life. For a time the two cavities communicate over the dorsal edge of the thick septum transversum by the paired pleural canals (Fig. 14). By the seventh week the peritoneal cavity is completely separated from the pleural canals by the pleural-peritoneal membranes.

Initially the peritoneal cavity is separated into right and left halves by the primitive gut and its mesentery. The mesentery is designated as ventral or dorsal, according to its relationship to the gut (Fig. 15). The ventral mesentery then disappears, except for the lesser omentum and falciform ligament, its contributions to the diaphragm and the suspensory ligament of the bladder. With resorption of the greater part of the ventral mesentery, the coelom becomes a single cavity.

That portion of the gut which will become the second part of the duodenum gives rise

Figure 15. Cross section through the level of the foregut. The peritoneal portion of the coelom (C) is initially divided into two cavities by the gut, the transient ventral mesentery (V) and the dorsal mesentery (D).

Figures 20 through 23: The peritoneal cavity and retroperitoneal space, viewed from the ventral aspect, as successive structures are removed:

Figure 20 View of the abdominal viscera following removal of the anterior abdominal wall. The two halves of the diaphragm are elevated to display the right anterior-superior and the left suprahepatic spaces, separated by the falciform ligament. The greater omentum is seen as if "hanging down" from the greater curvature of the stomach.

Figure 22. View of the posterior abdominal wall following removal of the viscera, except for the duodenum. The obliquity of the root of the mesentery is shown. The mesentery measures only 15 cm. in length at its attachment to posterior parietal peritoneum and 700 cm. in length at its attachment to small bowel. The paracolic gutters, communicating with the pelvis and subphrenic regions, are shown. The right gutter is particularly important in the spread of peritoneal infection.

Figure 21. View of the abdominal viscera as seen in Figure 20, except that the greater omentum has been removed. The liver is elevated, showing the right subhepatic and the left anterior-inferior subphrenic spaces.

Figure 23. View of the principal retroperitoneal structures after removal of the posterior parietal peritoneum and the vessels of the large bowel. The vessels of the colon become retroperitoneal only because the dorsal mesentery of the colon fuses with posterior parietal peritoneum. The ureters are the next most anterior structure of the retroperitoneum.

Figure 19 Diagrammatic sagittal section through a fetus, showing the relations of the greater and lesser peritoneal sacs. The two layers of the greater omentum have not yet fused. Basically the greater omentum is the dorsal mesentery of the stomach which has fused with the transverse mesocolon.

the root of the mesentery and the manner in which the mesenteries of the descending colon and ascending colon become fused with the posterior parietal peritoneum.

ANATOMY

Gross Anatomy. The peritoneal cavity was mentioned in the Papyrus Ebers some 3500 years ago, but it was not thoroughly described until 1730, when James Douglas of Edinburgh published a lucid account which has not been appreciably improved upon to this day.

The peritoneum is a serous membrane which lines the peritoneal cavity and invests a number of abdominal structures. Except for the openings of the fallopian tubes, the peritoneum is a completely closed sac. In a strict sense, the peritoneal cavity does not contain any organs, since the entire gastrointestinal tract and its derivatives are really retroperitoneal in position. It is customary to speak of those structures which are almost completely enfolded by peritoneum, such as stomach, jejunum, ileum, transverse colon, sigmoid colon, appendix, cecum, liver, gall-bladder and the spleen, as being "intraperitoneal."

That portion of the peritoneum which invests the intraperitoneal organs, and which makes up the coverings of the mesenteries, is the *visceral peritoneum*. That portion which lines the anterior, lateral and posterior abdominal walls, the undersurface of

the diaphragm and the floor of the pelvis is the *parietal peritoneum*. Although these are parts of the same membrane, the distinction is of some importance in regard to differences in sensory innervation.

The peritoneum of the anterior and lateral abdominal wall is reinforced by the transversalis fascia. This fascia is intimately associated with peritoneum in some areas where it strengthens this membrane. Elsewhere it may be separated from the peritoneum by a layer of fatty and areolar tissue.

The peritoneal cavity is divided into the general peritoneal cavity, or greater sac, and the lesser sac (Fig. 19). The latter has, as its only natural opening, the foramen of Winslow. It is bounded anteriorly by gastrophrenic ligament, stomach and gastrosplenic ligament and by parietal peritoneum posteriorly.

Hanging from the transverse colon and covering much of the ventral aspect of the lower abdominal viscera is the greater omentum (Fig. 20). This structure has a rich vascular supply and carries a variable amount of fat.

The surface area of the peritoneum is about 2 square meters and approximates that of the skin. Unlike skin, however, the peritoneum is a highly permeable membrane and this fact has a number of important physiologic implications.

Normally the peritoneal cavity contains 75 to 100 cc. of clear, straw-colored fluid, which facilitates the normal lubricating function of the membrane.

Microscopic Anatomy. The peritoneum consists of a surface layer of mesothelium and a deeper loose connective tissue layer containing collagen and elastic fibers, fat cells, reticulum cells and macrophages. The mesothelium is a simple squamous cell layer. As a result of irritation, these cells may become cuboidal and enclose small cystic spaces, a reaction which the pathologist must distinguish from neoplasia.

Normal peritoneal fluid contains 2000 to 2500 cells per cu. mm. The majority of these are macrophages with some desquamated mesothelial cells and lymphocytes. There are few polymorphonuclear neutrophils or eosinophils, but the number of granulocytes is greatly increased in the presence of inflammation. Peritoneal aspiration may be of value, not only to obtain fluid for culture and chemical analysis, but also because immediate study of the cells

may be *primary* or *secondary*. The most frequently encountered type is an *acute bacterial inflammation of the peritoneum*, which is almost always *secondary to contamination*. This particular variety of peritonitis is usually called, simply, "peritonitis" without any qualification.

Peritonitis due to contamination is common because the peritoneum is, to coin a phrase, a serous sac completely surrounded by pathogens. Within it is the gastrointestinal tract teeming with microorganisms. Externally the environment harbors streptococci and staphylococci. Above and below are the lungs and the pelvic organs, occasionally a source of bacteria which invade the peritoneal cavity.

HISTORICAL

Peritonitis has been well known since antiquity and death from peritonitis has been the terminal event in many disease processes.

Inability to prevent or to effectively treat peritonitis was the chief obstacle to the early development of abdominal surgery. In the pre-Listerian era, laparotomy was almost invariably followed by the development of peritonitis* and this infection, once established, progressed in most cases to a fatal outcome. A considerable part of modern surgical "ritual" in abdominal surgery is directed at the prevention of infection, particularly infection of the peritoneum. This includes scrubbing the hands, use of gowns, gloves, masks and numerous other details of technique.

ACUTE BACTERIAL PERITONITIS SECONDARY TO CONTAMINATION

Incidence. In 5 to 7 per cent of all autopsies, peritonitis is the primary, or a contributory, cause of death. Generalized peritonitis, while no longer the overwhelming problem it once was, is still the most common cause of death following abdominal surgery.

Etiology. Maingot states that the common lesions responsible for acute secondary bacterial peritonitis are: (1) appendicitis (40 per cent), (2) perforated peptic ulcer (20

* It is remarkable that between 1809 and 1829 Ephraim McDowell removed eleven ovarian cysts

per cent), (3) operative contamination (20 per cent), (4) pelvic inflammation (7 per cent), (5) intestinal obstruction and strangulation (7 per cent), (6) rupture of the intestine (2 per cent).

The species and virulence of the infecting organisms are important in determining the severity of the peritonitis.

A wide variety of organisms may be responsible for peritonitis and not infrequently more than one species of bacterium may be involved. It may be difficult to determine the relative pathogenicity of each organism, as organisms often act synergistically to produce severe systemic effects.

The organisms frequently found in peritonitis are: (1) *Escherichia coli*, (2) streptococci (both aerobic and anaerobic), (3) staphylococci, (4) pneumococci, (5) Friedlander's organisms, (6) *Pseudomonas aeruginosa*, (7) gonococci, (8) *Proteus vulgaris*, (9) *Clostridium perfringens* and other anaerobes.

The two most common and important pathogens are *E. coli* and *Streptococcus pyogenes*. This may be of some importance, as all streptococci are sensitive to penicillin, whereas the coliforms, which usually exist concomitantly, not only resist penicillin but destroy it by producing penicillinase. In a pure infection, the hemolytic streptococcus produces a highly virulent and rapidly lethal infection, whereas the coliforms tend to produce a relatively low-grade infection.

The degree of contamination is an additional factor in determining whether the infection will be rapidly walled off and controlled or whether the infection will spread and become generalized in the peritoneal cavity.

The role of bacterial toxins in producing the lethal effects of peritonitis is unsettled, but there is evidence that toxins produced by clostridia and endotoxins from lysis of coliforms play a part in the peripheral circulatory failure that marks the end stage of the disease.

Pathogenesis. It is important to appreciate the manner in which infection is disseminated in the peritoneal cavity and the way in which the peritoneum reacts to combat infection. Insight into this physiologic process enables one to assist the peritoneum and avoid interfering with its beneficial activity by misguided therapeutic efforts.

The outcome of peritonitis depends upon the number and virulence of the infecting organisms and the resistance of the host. In

the advantage of not having a hospital to serve as a reservoir of infection. The operations were carried out in his own home in Danville, Kentucky.

in the fluid may facilitate the diagnosis of tumors, inflammatory conditions and intraperitoneal trauma.

PHYSIOLOGY

Relation to Extracellular Fluid Compartment. Since the peritoneum is a highly permeable membrane of considerable surface area,* peritoneal fluid is a physiologically active collection constituting part of the extracellular fluid. Deuterium oxide (heavy water) placed in the peritoneal cavity very rapidly becomes equilibrated with the plasma and interstitial fluid of the patient. The intraperitoneal route of fluid administration is used in experimental animals. Not only are water, electrolytes and urea nitrogen rapidly transported across the peritoneal membrane, but endogenous and exogenous toxic substances are freely absorbed. Rapid absorption of bacterial toxins is one of several reasons for the very high mortality in untreated peritonitis. In bowel obstruction with distention and impairment of circulation, transperitoneal absorption of bacterial toxins, even without peritonitis, is probable. Furthermore, antibiotics instilled into the peritoneal cavity are very rapidly absorbed and may exert toxic effects upon the whole organism.

In addition to the intimate relation of peritoneum to the circulating blood, there are communications between the peritoneal and pleural cavities which appear to be independent of the blood stream. In cases of Meigs' syndrome, colloidal radioactive gold (Au^{198}) instilled into one serous sac rapidly appears in the other, probably as a result of transdiaphragmatic lymphatic transport.

Sensory Innervation. The parietal peritoneum is well supplied with somatic afferent nerves and is sensitive to all forms of stimuli. This is particularly true of the anterior parietal peritoneum, which, along with the rest of the anterior abdominal wall, is supplied by the lower six thoracic nerves. The parietal peritoneum posteriorly and in the pelvis is somewhat less sensitive. The ability of the parietal peritoneum to initiate the sensation of sharp pain in response to an inflammatory process in its vicinity is of the utmost importance in the diagnosis of an acute abdominal condition.

Moreover, the nervous pathways from re-

ceptors in the parietal peritoneum, and particularly in that of the anterior abdominal wall, permit fairly accurate localization of the source of the painful stimuli. When the parietal peritoneum is the source of a painful sensation, the area of pain indicated by the patient is of considerable diagnostic significance. The parietal peritoneum of the undersurface of the diaphragm is no exception to this rule and painful stimuli in the peripheral part are perceived in the vicinity of the adjacent body wall. Painful stimulation to the parietal peritoneum beneath the central diaphragm, although it is fairly accurately localized, is felt in the shoulder region as a result of *central misinterpretation*. The pain is sharp and the patient is able to indicate quite definitely where his pain is located in the neck or shoulder, a situation quite different from the perception of dull and vaguely localized pain from visceral stimulation.

In addition to causing sharp and well-localized pain, stimulation of the parietal peritoneum may cause involuntary rigidity of the abdominal musculature, tenderness, referred tenderness and rebound tenderness, if the stimulus is sufficiently intense. These characteristics identify the parietal peritoneum as the source of the pain, identify the pain stimulus as being inflammatory (which it almost always is) and, further, localize the site of the stimuli. Without the pain fibers of the parietal peritoneum, the clinical diagnosis of an "acute abdomen" would be impossible.

The visceral peritoneum is relatively insensitive, but it does register stimuli if they are sufficiently strong or prolonged, particularly in the presence of pre-existing inflammation. The root of the mesentery is quite sensitive to traction.

Most visceral afferent nerve fibers for pain run in the splanchnic nerves to the same six segments of the cord that receive somatic afferent fibers. The stimulus of visceral sensation is usually tension, whether the result of increased intraluminal pressure or increased tissue pressure from inflammation. Visceral pain is usually dull and vaguely localized to the central portion of the abdomen, although there are some exceptions to this rule, notably visceral pain initiated by the biliary tree.

INFLAMMATION OF THE PERITONEUM

Peritonitis is an inflammation of the peritoneum. The process may be *acute* or *chronic*, it may be *septic* or *aseptic* and it

*face of a Skeggs-Leonards artificial kidney.

The most important of these is the *translocation of fluid, electrolytes, and protein into a "third space"* where they are, for the time, lost to the body economy. There are really three subdivisions of this "third space":

1. The *peritoneal cavity*, where fluid is lost primarily by "weeping" of the peritoneum. Fluid lost by exudation has an electrolyte and nitrogen content similar to that of extracellular fluid. In addition, fluid may be lost into the peritoneal cavity by outpouring from the alimentary canal, the biliary tree, the pancreas or the urinary tract.
2. The loose connective tissue beneath the mesothelium of the bowel, mesenteries and parietes, where protein rich fluid accumulates as edema of the peritoneum.
3. The atonic, dilated gastrointestinal tract where fluid of varying chemical composition is deposited.

Because of this loss of fluid into the third space, many surgeons have appropriately compared the physiologic derangement in peritonitis to that of an extensive burn. The comparison is valid in that there is temporary sequestration of a large amount of fluid having approximately the same composition as plasma. The analogy falls down somewhat in that in a burn there is a variable degree of hemolysis of red cells with early anemia and excess potassium in the extracellular compartment. The latter change is not seen in early stages of peritonitis unless there is associated renal failure.

In addition to loss of fluid into a third space, there are other physiologic derangements. Oral intake is not possible, vomiting and, rarely, diarrhea may occur. Renal function is the principal mechanism for the protection of the organism against dehydration and biochemical imbalance. The intravenous therapy which the patient receives aids renal function and contributes to fluid and electrolyte equilibrium. A "stress reaction" will alter renal function and the composition of body fluids and this reaction may be magnified by surgical measures employed in the treatment of the peritonitis.

The effect of peritonitis on the fluid and electrolyte balance of the body, provided that it is not modified by therapy, is the production of a metabolic, hypokalemic alkalosis with marked dehydration.

As in the case of a burn, fluid sequestered in the third space eventually is reabsorbed and becomes available to the economy with the production of diuresis if the patient has

been well maintained. In the burned patient, diuresis can be expected to commence between forty-eight and seventy-two hours, but no such simple rule can be given for the patient with peritonitis. Usually a longer period must elapse before the third space begins to release its fluid to the circulation.

It has been pointed out by Davis that the shock seen in peritonitis is due to several causes, including: (1) reduction of the plasma volume, (2) myocardial damage due to bacterial toxins, (3) widespread vasodilatation due to bacteria or their toxins, (4) adrenocortical insufficiency, (5) fat embolism, (6) hepatorenal insufficiency.

Clinical Manifestations. The clinical course of acute bacterial peritonitis secondary to contamination is highly variable. In an overwhelming peritonitis the patient may succumb within a few hours from toxemia and shock. More often the fatal case terminates after a difficult downhill course of three to seven days. As a result of improved therapy the natural history of the disease today is localization of the infection with gradual control of the process. Some cases of peritonitis masquerade as "prolonged postoperative ileus" and may be undiagnosed.

Symptoms and History. If the patient is seen early in the course of his disease, the symptoms may do no more than suggest a diagnosis, which must be confirmed by examination or, in some cases, a period of observation. Even if the diagnosis of peritonitis is obvious, a detailed history is of considerable importance in establishing the nature of the initial lesion, as management may be contingent upon this consideration.

Pain may vary in intensity but is the most important and constant symptom. Visceral pain, which may be either steady or crampy, is vague and poorly localized. Pain produced by irritation of the parietal peritoneum is usually sharp, well localized, and virtually pathognomonic of an inflammatory process. The fact that it can be localized is of diagnostic importance. Changes in the location and intensity of pain originating in the parietal peritoneum may yield valuable information during a period of observation. Increasing pain and pain not relieved by drugs suggest spread of peritonitis. Pain is likely to be most intense over the spreading edge of the inflammatory process. Pain which subsides in intensity and decreases in area suggests a localizing process. The pain experienced by elderly and debilitated patients is minimal and not always in keeping

addition, the peritoneum exhibits certain peculiar weaknesses and special defensive powers.

The first weakness of the peritoneum is its proximity to the greater part of the gastrointestinal tract with its large bacterial population. Furthermore, the whole of the peritoneal cavity is a continuous space through which a contaminant may be rapidly spread and freely disseminated, especially with the aid of respiratory, intestinal and abdominal movements. Dissemination may be aided by the outpouring of fluid into the cavity. Moreover, mucus and partially digested intestinal contents from a bowel perforation promote multiplication and dissemination of bacteria and interfere with phagocytosis. Early localization by fibrinous adhesions may be overcome by an outpouring of intestinal contents or pus, by the pressure of increasing inflammatory exudate and by gas from bacterial fermentation. The extensive absorptive surface of the peritoneum permits rapid absorption of the bacterial toxins.

The peritoneum, like any other tissue, reacts to an irritant by inflammation and thus is the basic defense mechanism. The essence of inflammation is phagocytic activity, aided by humoral agents and the vascular response. The peritoneal membrane is exceptionally well adapted to produce an *effective inflammatory reaction and to combat infection*, provided the contamination is not massive or prolonged. A second and rather specific mechanism by which the peritoneum defends itself is by localization of an irritant. Localization is accomplished by bowel, mesentery and particularly omentum adhering to inflamed areas. At the site of inflammation these structures are arrested by the abundant, sticky, fibrinous exudate which progressively increases the adherence of the localizing structures. Approximately thirty-six hours is required for the formation of reasonably secure fibrinous adhesions which will protect against diffuse peritonitis. Localization of infection is further aided by sympathetic inhibition of peristalsis to produce a "paralytic" ileus. It is true that prolonged ileus may kill the patient because of the effects of distention and inanition, but it provides temporary protection against continued spread of the peritonitis.

These factors cited above determine whether or not the patient will survive. If the organisms are virulent and contamination is sudden and massive, if the infection is rapidly disseminated over the whole of

the peritoneal cavity or if attempts at localization by the peritoneum are thwarted by injudicious surgery or by stimulation of the bowel, the infection may become overwhelming. If the organisms are less virulent, if there is no source of continuing contamination, if drainage is provided for those cases in which increasing pressure in a poorly walled-off area would otherwise soil the remainder of the peritoneum, if the efforts of the peritoneum to localize the infection are respected, if the patient is adequately supported by intravenous therapy and by gastrointestinal decompression and if the number of pathogens can be kept below the critical level by antibodies and by antibiotics, then the cellular defenses of the peritoneum can be expected to overcome the infection.

Pathology. Acute bacterial peritonitis secondary to contamination may be either generalized or localized.

In *generalized peritonitis* the peritoneal cavity contains several hundred cubic centimeters of fluid, which may be thin, watery and odorless in the case of a hemolytic streptococcal infection, or which may be purulent, contain flakes of fibrin and have a strong fecal odor in the case of coliform infection. The entire bowel is dilated, its serosa is congested, edematous and covered with a purulent or fibrinous exudate which *may glue together the loops of small bowel*. Between the loops of intestine may be loculated collections of pus. The omentum is usually attracted to the site of the infection, but it may occupy a normal position or be matted into a firm mass. The subperitoneal vessels are dilated and there is edema of the areolar tissue beneath the mesothelium. The process may go on to abscess formation, repair by fibrosis or complete resolution.

In *localized peritonitis* the changes will be similar but confined to one portion of the peritoneal cavity by adherence of mesentery, bowel and omentum to the source of contamination. After a week or ten days, when the adhesions have become fibrous, the walled-off area may gradually become converted into a shaggy walled abscess.

The microscopic findings include congestion, edema and leukocytic infiltration, with patchy areas of tissue necrosis.

Pathophysiology. An understanding of some of the clinical manifestations of peritonitis, as well as a rational approach to therapy, is contingent upon an appreciation of the physiologic aberrations which occur

Figure 24. Supine x-ray of abdomen, generalized peritonitis (postoperative). Marked dilatation of large and small bowel is seen and there is thickening between adjacent intestinal loops.

spread (Fig. 24). Jejunum, ileum and colon contain air and can be identified by their typical patterns. The dilatation is usually less than in mechanical obstruction and the distribution of small bowel, while central, forms a "mosaic" pattern rather than horizontal loops with sharp hairpin turns as seen in mechanical obstruction. There is diffuse haziness, due to accumulation of exudate, with obliteration of the peritoneal fat line and psoas shadows. There is thickness of bowel wall between adjacent gas shadows due to edema of the bowel wall and the exudate. Free gas may be seen if peritonitis is due to perforation of bowel. Contrast studies are generally unnecessary and the administration of barium by mouth is contraindicated.

Periodic blood chemistry determinations may be of considerable value as guides to the supportive therapy of the patient.

The white blood count is almost always markedly elevated with a preponderance of polymorphonuclear granulocytes.

Diagnosis. There is no substitute for experience in developing diagnostic acumen in the management of patients with peritonitis. The salient clinical features, stated briefly, are: (1) abdominal pain, sharp, steady and localized, (2) the signs of irritation of the parietal peritoneum; (3) a silent abdomen. As Maingot points out: "It is

easier to diagnose the presence than the cause of peritonitis."

Differential Diagnosis. The differential diagnosis is that of an "acute abdomen."

Complications. Paralytic ileus, inanition, dehydration, electrolyte abnormalities, toxemia and shock are usually considered characteristic features of the disease, rather than complications. Septicemia and spread of infection by lymphatics to the retroperitoneum are less common and may be considered complications. The spread of localized peritonitis to become a diffuse infection is, at the same time, a complication of one and the pathogenesis of the other.

When a patient lives beyond a seven- or eight-day period and the infection persists, this may lead to so-called *chronic septic peritonitis* in which there are numerous pockets of pus walled off by adhesions and coils of bowel. These patients frequently die of toxemia or paralytic ileus or from mechanical bowel obstruction.

A much more common outcome is a localized version of the same process, an intraperitoneal abscess. Most abscesses are confined to their site of origin (e.g., peri-appendiceal) or are pelvic. Therapy is frequently directed toward obtaining localization of the infection in the pelvis. Less common is the subphrenic abscess, difficult of diagnosis and exacting in management.

Another complication which can occur after peritonitis is mechanical small bowel obstruction due to fibrinous adhesions.

Prognosis. Thirty years ago one-third of patients with peritonitis could be expected to succumb. At the present time, with earlier and more accurate diagnosis, a better understanding of the deranged physiology, improved fluid and electrolyte therapy, the use of whole blood where indicated, sulfonamides and antibiotics, gastrointestinal decompression and safer anesthesia, the mortality is between 5 and 10 per cent.

Treatment. Prophylactic treatment. A number of special procedures such as pre-operative bowel preparation, use of drains when indicated and preservation of blood supply are particularly concerned with the prevention of postoperative peritonitis.

One question that repeatedly arises in connection with laparotomy for the purpose of preventing peritonitis is whether drainage should be carried out. An old axiom says: "When in doubt, drain." W. J. Mayo turned this about to read: "When in doubt, don't drain." The arguments against prophylactic drainage are: (1) the drain tract

with the underlying pathologic process. It is well to bear in mind that the posterior and pelvic portions of the parietal peritoneum are not very sensitive and an inflamed organ in these locations may exhibit a more advanced pathologic state than one might suspect from the severity of the pain.

Vomiting is also a common symptom, but its nature and mechanism vary with the stage of the disease. Early in peritonitis, vomiting is reflex in origin and the vomitus consists of gastric contents. Later it is said to be toxic and the vomitus is brownish or bile stained. In the terminal stages of the disease, vomiting accompanies paralytic ileus and the feculent bowel fluid wells up from the mouth without effort on the part of the patient.

Physical Findings. The diagnosis of peritonitis can usually be confirmed on the basis of the physical findings, but often examination is not as revealing as interrogation in suggesting the precipitating lesion. When the physical findings are equivocal, there is no substitute for repeated examination at frequent intervals. The abdomen should be touched thoroughly but gently re-examined.

In the early stages of peritonitis the vital signs (temperature, pulse, respiratory rate, blood pressure), which are indices of the systemic effects of the disease, may be normal or there may be only tachycardia and a low-grade fever.

The physical examination should be complete and not just confined to the abdomen. A red throat, a dilated fixed pupil, a few rales in a lung base, icterus or a diminished femoral pulse may provide a clue to the cause of abdominal pain. Rectal examination is an important part of the physical examination of the patient with an acute abdomen. Inflammation in the pelvis may not cause significant abdominal findings, but the exquisite tenderness elicited by rectal examination may be diagnostic.

The patient with peritonitis usually lies very still because he has found that all movements aggravate his pain. His thighs and knees may be flexed in order to relax his abdominal muscles. His breathing is shallow so as to avoid movements of the abdominal wall. After inspection is completed, the abdominal wall should be very gently palpated for minor degrees of involuntary guarding, all efforts being made to reassure the patient and eliminate voluntary contraction of abdominal muscles. Only after this maneuver is carried out should one complete the abdominal examination.

Guarding is of greater significance than tenderness, but once the patient has been hurt, it is difficult to detect minor degrees of this important physical finding. Point tenderness, referred tenderness and rebound tenderness on palpation, along with involuntary guarding, point to irritation of the parietal peritoneum. Their presence is important and their location corresponds to that of the underlying inflammatory area.

Auscultation of the abdomen must always be part of the abdominal examination. The stethoscope is the key to distinguishing pain due to simple obstruction from that due to peritonitis. The silent abdomen indicates peritonitis.

Percussion has its place in the examination of the abdomen but does not often yield valuable information. Generalized hyperresonance due to the presence of gas-filled bowel may be elicited in ileus. Occasionally, obliteration of the area of liver dullness will be found, suggesting free gas in the peritoneal cavity.

Examination for costovertebral angle and flank tenderness and the use of the psoas and internal obturator tests are also useful.

The Terminal Phase. In the end stages of the disease the previously high fever falls to normal or subnormal and the pulse becomes weak and very rapid, an ominous combination. The pain is severe and steady, the abdomen distended and silent and the vomiting is effortless. Hippocrates, who must have seen it often, described the dusky pallor, anxious expression, sunken staring eyes, dry, fissured tongue and wet skin that mark the end of the struggle as follows: ". . . if the eyelid be contracted, livid or pale, or also the lip or nose, along with some of the other symptoms, one may know for certain that death is close at hand. It is a mortal symptom, also, when the lips are relaxed, pendent, cold, and blanched." Death is due to peripheral circulatory and renal failure.

Laboratory Aids. The diagnosis of peritonitis is made on clinical grounds and laboratory aids may confirm the diagnosis. The most important of these is a series of plain x-ray films of the abdomen. Plain films of the abdomen should be taken in three positions: anteroposterior supine, anteroposterior upright and left lateral decubitus. If the peritonitis is localized there may be a segmental ileus of some part of the bowel in only one region of the abdomen. With general peritonitis, the dilatation of the gastrointestinal tract within the abdomen is wide-

appendicitis provided that: (1) the patient is an adult, (2) he is first seen between two and five days after the onset, (3) he is very ill and (4) the infection seems to be localizing satisfactorily. This Ochsner-Sherren treatment must be carried out "at the door of the operating room," that is, with continuous observation and readiness to intervene surgically if the peritonitis begins to spread. This plan has no place in the treatment of children and is only occasionally employed for adults.

When surgical intervention is indicated, a few hours of supportive measures may be required to prepare the seriously ill patient for operation.

What is to be done at laparotomy? First, the source of contamination is removed or closed off (appendix or perforated ulcer, respectively) or, in the case of a gallbladder with impending perforation, it may be simply drained. Secondly, intraperitoneal fluid or exudate is aspirated to decrease the massiveness of the contamination. Thirdly, if it appears advisable, a drain may be put down to the source of contamination or to the site where fluid is likely to collect. Finally, one may utilize the opportunity to guide a long tube, which is introduced through the usual nasal route, past the pylorus and into the small bowel. These maneuvers should be carried out as quickly as possible and without disseminating infection.

Assisting the peritoneum to localize and overcome infection. The great advances in modern drug therapy of infection should not be permitted to overshadow the importance of some basic and simple therapeutic measures. Rest for the patient and for his gastrointestinal tract is essential in order to permit localization of the peritonitis.

The site of localization is important, for should complete resolution of the infection fail and abscess formation result, the abscess will have to be located and drained. The pelvis is a very desirable location; the subphrenic region is a dangerous area for localization of an abscess. Coffey showed that when a patient lies flat in bed, the paracolic gutter is 1 inch lower than the pelvis and it is well known that the right paracolic gutter communicates with the subphrenic spaces on the right side (Fig. 22). To encourage drainage of fluid from the flank to the pelvis, the head of the bed must be elevated 60 to 70 degrees or, as

Fowler advocated, 8 to 14 inches higher than the foot of the bed. The patient's trunk, then, should be oblique, with the patient either flat on a sloping bed or else in a semisitting position. The knees should not be bent and if the patient tends to slip down in bed it is good for his venous circulation if he must push his feet against a footboard from time to time to regain his position.

Application of heat to the abdomen in the form of hot packs or diathermy will aid bodily defenses and after a few days the use of warm rectal irrigations may promote localization in the pelvis. The basic defense against infection is still phagocytosis, aided by other natural defense mechanisms. Drugs such as sulfonamides and antibiotics must play a secondary role in that they only assist these natural processes. Pulaski has shown that any antibiotic which suppresses the total number of microorganisms to below a critical value of about 1×10^7 per ml. of exudate permits the body's defenses to cope with the remaining bacteria. Thus, it is not necessary to give a specific drug to eliminate completely each of the several bacterial species which may be present; the objective is only to lower the bacterial population below the "critical level."

At the present time it appears that the drugs of choice for the treatment of peritonitis from intestinal contamination are oxytetracycline, chlortetracycline, chloramphenicol, the combination of streptomycin and penicillin, and the sulfonamides. Penicillin is very effective against all streptococci, but it is inactivated by the penicillinase produced by various coliforms. This can be overcome by the use of a penicillin-streptomycin mixture, the only antibiotic combination which appears to have any advantage over the administration of a single drug.

The dose of sulfonamide or antibiotic administered should be large enough so that the partially resistant strains are not just replaced by totally resistant organisms. At the same time, it is well to remember that these drugs are toxic substances and that it is not unusual to encounter complications which necessitate reduction of dose or change of drug. If renal function is inadequate, the blood level of the antibiotics may parallel that of the nonprotein nitrogen. Vitamin K should be given by vein when broad-spectrum antibiotics are given for more than a few days. The patient should

is a source of infection from the outside, (2) it is impossible to drain the peritoneal cavity; (3) a Penrose drain is ineffective after six or eight hours because it becomes sealed. All of these statements are true. It is possible and often desirable, however, to drain a localized portion of the peritoneal cavity. The last-named obstacle can be overcome by periodic loosening of the Penrose drain or by use of a sump (suction with air vent) drain. The decision as to whether to drain is often a matter of judgment and sometimes of personal preference. In general, prophylactic drainage is advised in cases of

1. A localized area of peritonitis around which secure adhesions have not yet formed

2. Surgery on the extrahepatic biliary tract

3. Injury to or surgery on the liver, where there is a possibility of bile leakage

4. A gastrointestinal suture line which is insecure and not protected by other measures (e.g., duodenal stump)

5. Possible continued leakage of fluid (blood, urine, pancreatic juice), even though it is sterile at the time of surgery

6. The involvement of a retroperitoneal area (e.g., retrocecal, retroperitoneal appendicitis with contamination).

A drain can be put down to the vicinity of the source of a fluid or contaminant or it can be placed to drain a low point to which fluid can be expected to gravitate (pelvis, paracolic gutter, Morrison's pouch), or both.

A second group of prophylactic measures, of no less interest to the surgeon, has to do with early diagnosis and treatment of lesions likely to culminate in peritonitis if not adequately treated.

Definitive treatment. The definitive treatment of bacterial peritonitis is based upon an understanding of the etiology and pathogenesis, the pathology and the physiologic derangements which have been discussed previously. Treatment can be resolved into five facets:

1. A decision must be made as to whether there is continuing contamination of the peritoneal cavity and, if there is, operative correction should be undertaken, provided other circumstances do not contraindicate surgical interference.

2. All possible measures must be carried out to assist the peritoneum in localizing the infection, preferably in a location favorable for future drainage, and in overcoming that infection.

3. The gastrointestinal tract must be decompressed with a long tube, while the defensive nature of the paralytic ileus is respected.

4. Supportive treatment should be given to maintain the patient through his illness, this includes relief of pain, treatment of shock, maintenance of fluid and electrolyte balance and correction of hypoproteinemia.

5. Repeated clinical observations must be made for confirmation of diagnosis, to ascertain effectiveness of therapy and to note the progress of the disease.

The question of surgical intervention. The decision of operative interference depends upon the primary lesion more than on any other single factor, but the time interval since the onset, the progress of the disease and the general condition of the patient will modify this decision. We have already pointed out that the peritoneum is well adapted to dealing with infection, but it will be overwhelmed by continuing contamination.

The influence of the primary lesion can be illustrated by some examples: If the peritonitis is due to acute diverticulitis with perforation, any infection will probably be well localized and the perforation will be small and readily sealed off by natural defenses. Operation in such a case if the diagnosis is certain, unless peritonitis is spreading, is useless and even harmful; treatment consists of intensive application of the "antiperitonitis regimen" (points 2 to 5, above) without surgical intervention. In the case of a perforated peptic ulcer, one usually operates in the first twenty-four hours, but not later. During the first twenty-four hours there is continuing contamination and a progressively poorer prognosis; after that the perforation has usually sealed off. In any case the patient is moribund from his generalized peritonitis, so that operation carries a higher risk than do active conservative measures alone. In acute appendicitis with generalized peritonitis, continuing contamination can probably be expected for several days and the appendix should be removed, especially in children, if the patient's condition is such that he will tolerate surgery. The mortality rate in this situation, generalized peritonitis from acute appendicitis, is about twice as high (13 per cent) with conservative treatment as it is with surgical removal of the appendix and intensive supportive measures.

Conservative measures are justified in the treatment of localized peritonitis from acute

case are as much the responsibility of the physician as are the initial diagnosis and original plan of management.

LESS COMMON TYPES OF PERITONITIS

Primary ("Idiopathic") Peritonitis. Primary peritonitis is an infection which is not secondary to an operation or a wound, to an inflammatory, perforative or other disease process in or near the peritoneal cavity or to known hematogenous spread of an infection elsewhere. Obviously, the origin of the disease is obscure and the term "idiopathic" seems appropriate.

Primary peritonitis was fairly common prior to the advent of sulfonamides and antibiotics, but it is rare today. The majority (75 per cent) of cases occur in girls, usually between the ages of two and ten, but it has been described at all ages.

About two-thirds of the cases of primary peritonitis are due to hemolytic streptococci and about one-third are due to pneumococci. Only a single organism is involved in any case; hence it differs from the "polymicrobial" character of most cases of secondary peritonitis. Occasionally, primary peritonitis is said to be due to coliforms, but such a diagnosis must always be suspect. About half of the pneumococcal cases occur in children with nephrosis.

One concept regarding the pathogenesis of primary peritonitis is that the organisms gain entry through the vagina and fallopian tubes. This is supported by the observation that the disease is one of the underprivileged classes and of unhygienic conditions. The alkaline pH of the vagina in children may account for the age incidence mentioned. Another suggestion has been that most of the infections are really hematogenous and the proponents of this theory point to a high incidence of an associated focus of infection. Neither view completely explains the sex distribution.

Streptococcal infections cause a fulminating infection with a watery, odorless exudate and the pathologic features of streptococcal peritonitis. Pneumococcal infections are less fulminating and cause a characteristic gelatinous, sticky, pale green, odorless exudate with abundant fibrin formation.

The child is most often (75 per cent) under five years of age. A pre-existing upper respiratory infection, otitis media or pneumonia may mask for a while the onset of the peritonitis. The main clinical features are rapid onset of diffuse abdominal pain, fever, often chills, restlessness, ir-

ritability, vomiting, diarrhea in half the cases, sometimes hematemesis or melena, and manifestations of extreme toxicity.

The child usually has a temperature of 104° F., looks very ill and may be markedly dehydrated with dry mucous membranes and sunken eyes. The abdomen may be protuberant and diffusely tender. There may be abundant fluid in the abdomen and sometimes shifting dullness can be demonstrated. The consistency of the abdominal wall varies from doughy in infants to boardlike in older children. Peristaltic activity is increased at first and is then followed shortly by paralytic ileus. In pneumococcal cases there may be cyanosis and herpetic lesions on the lips.

The white blood count usually ranges from 20,000 to 50,000 with polymorphonuclear neutrophils predominating. In cases superimposed on nephrosis there is a heavy albuminuria. Blood culture is usually positive for streptococci or pneumococci.

Pneumonia should be ruled out. This diagnosis may be difficult in cases where there is a paucity of physical and x-ray findings in the chest. A rapid respiratory rate and lack of abdominal tenderness will aid in the differentiation. The two conditions may co-exist.

A more difficult problem is the differentiation between primary peritonitis and secondary peritonitis, usually from a perforated appendix. The rapidity of onset and stormy course, particularly if accompanied by a chill, the finding of generalized rather than right-sided tenderness, the degree of fever and leukocytosis during the entire illness, the finding of a primary focus and a history of nephrosis or a finding of heavy albuminuria may favor a diagnosis of primary peritonitis.

The physician rarely accepts a diagnosis of primary peritonitis while acute appendicitis, which is far more common, remains a possibility. In moribund children and in instances where the diagnosis of primary peritonitis seems almost certain because of known nephrosis or a known coexisting focus of infection and septicemia, the matter may be settled by peritoneal aspiration under local anesthesia. A smear of the exudate showing pure streptococci or pneumococci will allow one to proceed servative therapy with assurance.

In the majority of cases the diagnosis may be made at exploration. A right flank incision can be very limited if one suspects a primary

be watched for any evidence of agranulocytosis, diarrhea or mycotic overgrowth in the mouth, pharynx and lungs.

The drugs should be given intravenously or intramuscularly in peritonitis. Rarely can the oral route be used. The question of intraperitoneal administration has not been settled as yet, this route appears to have advantages but 'is not without danger. Deaths from respiratory arrest have occurred as a result of intraperitoneal administration of neomycin Chlortetracycline, tetracycline and streptomycin have been shown to be toxic when given intraperitoneally to experimental animals.

Gastrointestinal decompression. The gastrointestinal tract must be decompressed to prevent the secondary effects of distention upon the circulation in the bowel wall and also upon the patient's respiratory and circulatory systems. This procedure helps one to estimate the amount of fluid lost into the bowel from the body's economy Gastric suction is effective to some degree, but the use of a long intestinal tube is preferable. High concentrations of oxygen by nasal catheter may lessen distention. A rectal tube and application of heat to the abdomen are of value after bowel function begins to return. The use of Prostigmine, Pitressin and all such drugs to stimulate the bowel is definitely contraindicated

Supportive therapy. The fluid and electrolyte requirements of the patient with peritonitis must be supplied by the intravenous route. The plan of treatment depends on calculation of the "static deficit," the "dynamic losses," and the "base line requirements," as outlined by Randall Estimation of the first of these, and to some extent the second, is nothing more than an "educated guess" and must be revised by noting the patient's response to therapy. It is helpful to realize that the fluid lost into the third space amounts to several liters and that its composition resembles that of plasma. The use of an indwelling catheter to make certain that a urine flow of 25 to 50 cc. per hour is being maintained, along with other clinical assessment of the state of hydration, will aid in determining the quantity of fluid to be administered.

One can judge the mineral requirements of the patient from the considerations just mentioned and serum electrolyte determinations. Some of the common pitfalls of fluid and electrolyte therapy must be kept in mind in the difficult task of caring for these patients:

1. A low serum sodium level of 125 to 130 mEq. per liter is to be expected for forty-eight to seventy-two hours after severe stress.

2. Serum potassium is a poor index of the intracellular level. Potassium should be withheld for forty-eight hours after surgery or in the presence of renal insufficiency or elevated nonprotein nitrogen. Otherwise it should be given at the rate of about 80 mEq per day in order to avoid intracellular depletion and prolonged ileus.

- 3 Overhydration is a danger in the elderly and after resorption from the third space begins

Depleted serum proteins must also be replaced by the administration of whole blood, serum albumin or plasma stored at room temperature. Protein hydrolysates can be used to reduce the degree of the negative nitrogen balance, provided that one can simultaneously supply enough calories in the form of glucose to meet the demands of the elevated metabolic rate. For the patient with prolonged ileus, intravenous fat preparations may be used to combat inanition

As a rule, the use of cortisone and hydrocortisone in the presence of an infection, and particularly if it is due to an ulcerative lesion of the gastrointestinal tract, is contraindicated. Their use is occasionally justified, however, in patients who show signs of adrenocortical insufficiency, i.e., persistent hypotension and vasoconstriction after adequate blood replacement and a high circulating eosinophil count. This state may result from previous adrenal disease, adrenal atrophy due to previous cortisone administration, or from adrenal exhaustion due to the peritonitis.

Relief of pain is part of supportive therapy. Morphine or meperidine (Demerol) should be administered often enough and in adequate dosage to guarantee the patient pain-free periods when he can obtain necessary rest.

Continued observation. Finally, the patient with peritonitis must be frequently reassessed. The diagnosis of the causative lesion, if it has not been confirmed by exploration, is not always clear cut. Response of the patient to the therapy administered should be evaluated several times daily during the acute phase of the illness Awareness of the complications of the disease and their treatment is essential. Repeated examination of the abdomen for evidence of localization or spread of the peritonitis requires careful observation of the

case are as much the responsibility of the physician as are the initial diagnosis and original plan of management.

LESS COMMON TYPES OF PERITONITIS

The physician rarely accepts a diagnosis of primary peritonitis while acute appendicitis, which is far more common, remains a possibility. In moribund children and in instances where the diagnosis of primary peritonitis seems almost certain because of known nephrosis or a known coexisting focus of infection and septicemia, the matter may be settled by peritoneal aspiration under local anesthesia. A smear of the exudate showing pure streptococci or pure pneumococci will allow one to proceed with conservative therapy with assurance.

In the majority of cases the diagnosis will be made at exploration. A right lower quadrant incision can be very limited in extent if one suspects a primary peritonitis. Gross

recommends the following procedure: (1) obtain some exudate for a smear to prove the diagnosis—this is done by an assistant immediately, not postoperatively—and culture, (2) confirm that the appendix is not the source of the infection; (3) put a small drain down into the right iliac fossa; (4) do not remove the appendix if it is normal. Postoperatively an antiperitonitis regimen should be followed. Sulfonamides and penicillin are the specific drugs of choice.

Bacterial Peritonitis Due to Hematogenous Spread. This entity is blood borne from a known infection elsewhere in the body, so that it is really a secondary peritonitis. It differs from contamination peritonitis in that it does not arise from a lesion in the vicinity of the peritoneum.

The source of the infection may or may not be apparent. Many surgeons believe that the majority of cases of so-called primary peritonitis actually arise from a hidden focus, are really hematogenous and so belong in this group. The fact that the majority of the organisms are streptococci and pneumococci favors this point of view.

The clinical features are identical to those which have been described for primary peritonitis.

This disease, like primary peritonitis, should be treated conservatively when the diagnosis can be made.

Tuberculous Peritonitis. Tuberculous peritonitis was at one time fairly common, but fortunately it is now rarely seen. It is almost always associated with tuberculosis elsewhere.

Tuberculous peritonitis is somewhat more common in females. Both children and adults may be affected, the usual age range being between ten and forty years.

The infecting organism is *Mycobacterium tuberculosis* of either the human or the bovine type. The primary lesion is most often tuberculous ulceration of the bowel, but infection may also arise from tuberculous mesenteric lymph nodes, tuberculosis of the fallopian tubes, lymphatic spread from the lung or pleura or hematogenous spread from distant sites.

Basically there are two types of tuberculous peritonitis—the “moist” variety and the “dry” form. Tubercles are found in both varieties, but they may not be immediately apparent on gross examination because of fibrinous or purulent exudate, caseation or fibrous adhesions. In the *dry form* there is usually a dense inflammatory exudate and numerous adhesions matting the coils of

bowel together. Fecal fistula formation may occur in either type, particularly in the dry form, and in children the fistula may communicate with the umbilicus. In the *moist form* the patient is likely to be a child and the ascites may be massive. The fluid is usually thin and lemon-yellow and it may coagulate spontaneously. Its specific gravity is over 1.018 and its protein content over 4 per cent, thus distinguishing the fluid from a transudate. The encysted variety is a combination of both of the above forms, with a localized area of fluid which may be mistaken for some other cystic lesion.

The condition is of fairly acute onset in two-thirds of the cases. The moist form is likely to run a more insidious course than the dry. There are systemic manifestations, consisting of wasting, anorexia, and fever, accompanied by abdominal pain, vomiting, diarrhea and enlargement of the abdomen. In the moist form the abdomen may become very distended and tense with dilatation of the veins of the abdominal wall and, if the tunica vaginalis is patent, a simulated hydrocele. Redness of the umbilicus may precede formation of a fecal fistula.

The diagnosis is usually not difficult, as there is evidence of tuberculous infection elsewhere. In the ascitic variety peritoneal fluid may be aspirated for culture and guinea pig inoculation. The differential diagnosis includes pyogenic peritonitis, carcinomatosis, other forms of ascites, abdominal tumor and celiac disease.

The chief complications are cachexia and intestinal obstruction. In the preantibiotic era the mortality was 40 per cent, death often being due to toxemia, tuberculosis elsewhere or rarely to amyloidosis.

The treatment consists chiefly of general supportive measures for tuberculosis, which should be carried out in a sanatorium. The use of the antituberculous drugs—streptomycin, para-aminosalicylic acid and isonicotinic acid hydrazide—have improved the prognosis markedly. In the ascitic variety, laparotomy and evacuation of the fluid seem to have a beneficial effect. In the dry form, operation should be avoided, except when made mandatory by intestinal obstruction. When laparotomy has been carried out in the presence of tuberculous peritonitis, drainage and exteriorization of bowel should be avoided.

Aseptic Peritonitis. Aseptic peritonitis is important for two reasons. A variety of sterile materials (e.g., foreign bodies, bile, blood, meconium) which may gain entrance

to the peritoneal cavity are irritants which set up aseptic inflammatory reactions giving rise to sequelae and clinical symptoms. Secondly, the chemical peritonitis produced by any of these substances may be followed by a superimposed bacterial peritonitis.

Foreign bodies may reach the peritoneal cavity from operative procedures, e.g., sponges, suture material, instruments. They may result from penetrating wounds, missiles and bits of clothing. The gastrointestinal and genitourinary tracts may be the source of fish bones, wood splinters, needles, pins and glass. Such foreign bodies usually cause one of three types of reaction: (1) bacterial inflammation in which the foreign body is incidental; (2) aseptic inflammation, which usually results in a localized sterile abscess as the peritoneum walls off the foreign body; (3) a similar process with formation of a sinus or fistula. The relative amounts exudation and fibrosis vary greatly with the nature of the foreign body.

The clinical manifestations of a sterile intraperitoneal foreign body are highly variable. A surgical sponge may give rise to an abscess with a mass, fever, chills, toxic manifestations and legal implications. This type of foreign body must be removed. Intraperitoneal shrapnel, if sterile, may be simply walled off by fibrous tissue and give rise to few if any manifestations in the emotionally stable patient. The surgeon must guard against being persuaded by the patient to undertake a search for this type of foreign body, on the basis of vague subjective complaints.

Bile may ooze through the wall of a gall-bladder which is distended but intact. More commonly, bile reaches the peritoneal cavity as a result of biliary tract rupture or as a sequel to operations on the biliary system. Sterile bile is a mild irritant in its own right, but should it become secondarily infected, it may give rise to a virulent type of peritonitis. To prevent this unfortunate sequel, the adequate routine drainage of Morrison's hepatorenal space is recommended after biliary surgery or liver trauma.

Blood is only a mild irritant and it is slowly absorbed. However, blood in the peritoneal cavity may serve as a nidus for bacterial infection. For this reason it should always be evacuated at the end of an operation. An oozing surface, capable of producing hematoma, should be drained.

A most interesting entity is *meconium* or fetal peritonitis, which was first described by Sir James Young Simpson in 1835. The

disease results from perforation of the bowel and inflammation of the peritoneal membrane due to sterile meconium. The perforation of the intestine may occur any time from the third fetal month to the neonatal period. It may result from meconium ileus, congenital diverticula, atresia, stenosis, congenital bands, hernia, volvulus or intussusception. If the opening is still present at birth or if perforation occurs after birth, secondary bacterial infection is a rule and the outlook in such cases is very poor.

Gastric juice is very irritating and the chemical peritonitis which is set up by a perforated ulcer is followed, after several hours, by bacterial infection. Sterile urine from traumatic intraperitoneal rupture of the bladder is also an irritating fluid and this chemical insult is frequently followed by secondary infection. These lesions must be diagnosed early and treated by appropriate operation.

Intraperitoneal pancreatic juice usually becomes infected and in hemorrhagic pancreatitis superadded bacterial infection should always be anticipated. Intensive antibiotic therapy deals adequately with this infection in most instances, but occasionally an abscess or collection will have to be drained ten to fourteen days after the onset.

GRANULOMATOUS LESIONS OF THE PERITONEUM

Separation of foreign body granulomas of the peritoneum from aseptic peritonitis due to foreign bodies is somewhat arbitrary. The basic pathologic process is the same—the response of the peritoneum to a noninfected irritant. The varying degrees of exudation and fibrosis distinguish the two reactions.

Some of the substances which are more commonly reported as causes of granulomatous reaction by the peritoneal membrane are: talc, starch, lycopodium spores, mineral oil and silica. These etiologic agents are often introduced into the peritoneal cavity by the surgeon.

In the past, granulomatous lesions due to talc were often seen, because this substance was widely used as a glove powder. Talc is composed mainly (83 per cent) of hydrated magnesium silicate and incites a very intense fibroblastic reaction which may give rise to dense adhesions within a few weeks, or the process may take years. In an attempt to overcome this problem, powdered starch was introduced as a glove powder by Lee and Lehman. The starch is made from either corn or rice and should be relatively in-

recommends the following procedure. (1) obtain some exudate for a smear to prove the diagnosis—this is done by an assistant immediately, not postoperatively—and culture, (2) confirm that the appendix is not the source of the infection, (3) put a small drain down into the right iliac fossa, (4) do not remove the appendix if it is normal. Postoperatively an antiperitonitis regimen should be followed. Sulfonamides and penicillin are the specific drugs of choice.

Bacterial Peritonitis Due to Hematogenous Spread. This entity is blood borne from a known infection elsewhere in the body, so that it is really a secondary peritonitis. It differs from contamination peritonitis in that it does not arise from a lesion in the vicinity of the peritoneum.

The source of the infection may or may not be apparent. Many surgeons believe that the majority of cases of so-called primary peritonitis actually arise from a hidden focus, are really hematogenous and so belong in this group. The fact that the majority of the organisms are streptococci and pneumococci favors this point of view.

The clinical features are identical to those which have been described for primary peritonitis.

This disease, like primary peritonitis, should be treated conservatively when the diagnosis can be made.

Tuberculous Peritonitis. Tuberculous peritonitis was at one time fairly common, but fortunately it is now rarely seen. It is almost always associated with tuberculosis elsewhere.

Tuberculous peritonitis is somewhat more common in females. Both children and adults may be affected, the usual age range being between ten and forty years.

The infecting organism is *Mycobacterium tuberculosis* of either the human or the bovine type. The primary lesion is most often tuberculous ulceration of the bowel, but infection may also arise from tuberculous mesenteric lymph nodes, tuberculosis of the fallopian tubes, lymphatic spread from the lung or pleura or hematogenous spread from distant sites.

Basically there are two types of tuberculous peritonitis—the “moist” variety and the “dry” form. Tubercles are found in both varieties, but they may not be immediately apparent on gross examination because of fibrinous or purulent exudate, caseation or fibrous adhesions. In the dry form there is usually a dense inflammatory exudate and numerous adhesions matting the coils of

bowel together. Fecal fistula formation may occur in either type, particularly in the dry form, and in children the fistula may communicate with the umbilicus. In the moist form the patient is likely to be a child and the ascites may be massive. The fluid is usually thin and lemon-yellow and it may coagulate spontaneously. Its specific gravity is over 1.018 and its protein content over 4 per cent, thus distinguishing the fluid from a transudate. The encysted variety is a combination of both of the above forms, with a localized area of fluid which may be mistaken for some other cystic lesion.

The condition is of fairly acute onset in two-thirds of the cases. The moist form is likely to run a more insidious course than the dry. There are systemic manifestations, consisting of wasting, anorexia, and fever, accompanied by abdominal pain, vomiting, diarrhea and enlargement of the abdomen. In the moist form the abdomen may become very distended and tense with dilatation of the veins of the abdominal wall and, if the tunica vaginalis is patent, a simulated hydrocele. Redness of the umbilicus may precede formation of a fecal fistula.

The diagnosis is usually not difficult, as there is evidence of tuberculous infection elsewhere. In the ascitic variety peritoneal fluid may be aspirated for culture and guinea pig inoculation. The differential diagnosis includes pyogenic peritonitis, carcinomatosis, other forms of ascites, abdominal tumor and celiac disease.

The chief complications are cachexia and intestinal obstruction. In the preantibiotic era the mortality was 40 per cent, death often being due to toxemia, tuberculosis elsewhere or rarely to amyloidosis.

The treatment consists chiefly of general supportive measures for tuberculosis, which should be carried out in a sanatorium. The use of the antituberculous drugs—streptomycin, para-aminosalicylic acid and isonicotinic acid hydrazide—have improved the prognosis markedly. In the ascitic variety, laparotomy and evacuation of the fluid seem to have a beneficial effect. In the dry form, operation should be avoided, except when made mandatory by intestinal obstruction. When laparotomy has been carried out in the presence of tuberculous peritonitis, drainage and exteriorization of bowel should be avoided.

Aseptic Peritonitis. Aseptic peritonitis is important for two reasons. A variety of sterile materials (e.g., foreign bodies, bile, blood, meconium) which may gain entrance

smooth postoperative course with nothing unusual except for a low-grade fever and slight increase in pulse rate about the time that discharge from hospital is being considered. Later the temperature spikes to 101° or 105° F. and chills are not unusual. There may be associated anorexia, nausea and vomiting. Constipation and some abdominal distention may result from a localized area of paralytic ileus. In long-standing cases there may be marked weight loss.

The patient with an abscess usually looks ill. He may be dehydrated and either flushed from fever or pale from associated anemia. Usually a mass is palpated in the right iliac fossa on abdominal examination and there is associated tenderness and guarding. The mass may be palpable by rectal examination and may be fluctuant. When an abscess is present leukocytosis is usually marked with a predominance of polymorphonuclear neutrophils.

Periappendiceal abscess may give rise to other complications, including generalized peritonitis, spontaneous drainage into the bowel, fecal fistula, pylephlebitis, paralytic ileus, mechanical bowel obstruction, septicemia and death.

Many cases of periappendiceal abscess resolve with conservative treatment alone. In such cases the patient probably has only an indurated mass with a low-grade fever and minimal symptomatology. A patient with a high spiking fever will certainly require surgical intervention, as well as supportive measures, the latter consisting of antibiotics, bed rest, heat to the abdomen, relief of pain, intravenous fluids, electrolytes, glucose and sometimes blood as well as intubation. The very ill patient with a hectic fever requires adequate drainage of the abscess as soon as dehydration and ketosis are corrected.

The operation for periappendiceal abscess has three objectives: (1) to drain the abscess, (2) to avoid contamination of the general peritoneal cavity, (3) to remove the appendix. The first two are essential, the third is not. Although the majority of appendices in such circumstances can be removed, it is better to leave the appendix than to disseminate infection. An extraperitoneal approach should be used, a small incision being made either over the most prominent part of the mass or else lateral to the mass. If it becomes apparent that the uninvolved peritoneal cavity will be traversed, the wound should be closed and a more suitable site for incision chosen. Needle

aspiration is a blind procedure and is neither safe nor adequate. The pus should be completely evacuated and a Penrose drain placed in the depth of the cavity.

Pelvic Abscess. A pelvic abscess may result from disease which is primary in that location or by gravitation of infected exudate from peritonitis elsewhere into the pelvis. The latter development is encouraged by positioning of the patient, because if abscess formation cannot be avoided, the pelvis is a relatively favorable location. A pelvic abscess is preferable to a subphrenic abscess because: (1) it does not interfere with respiratory function; (2) it is relatively easy to diagnose; (3) it is easy to drain or if drainage is spontaneous it is usually into the

resc. abscess
abscess
in almost every respect. One significant difference, however, is that pelvic abscess is often characterized by diarrhea. Pain, tenderness and guarding are usually less marked and, of course, the mass is not felt as well abdominally as it is by rectal or bimanual examination.

Supportive therapy of a pelvic abscess is similar to that for a periappendiceal abscess, except that if the mass is not fluctuant, it may be encouraged to point toward the rectum by means of warm enemas. The daily rectal examinations, which are carried out to evaluate the abscess, may be enough to encourage "spontaneous" rupture into the rectum.

If "spontaneous" rupture does not occur, severe symptoms and finding of fluctuation may serve as criteria for operative intervention. The abscess may be opened through the posterior fornix of the vagina, if the abscess lies in the cul-de-sac in the female, or through the anterior wall of the rectum. These approaches should be used rather cautiously, because a loop of adherent bowel may be mistaken for loculated pus. If the rectal route is chosen, dilatation of the anal sphincter will promote continuous drainage. If the abscess is not pointing toward rectum or vagina, and particularly if the mass can be felt suprapubically, it is better to open it by an abdominal incision and by an extraperitoneal route.

Subphrenic Abscess. A subphrenic abscess is an abscess located in the space between the diaphragm and the transverse mesocolon. These abscesses are not common, compared to other intraperitoneal abscesses. They are important because they are difficult to diag-

nocuous because it is gradually absorbed by the peritoneum. Unfortunately, it has been found that starch may also give rise to a foreign-body reaction, although less frequently and to a lesser degree than talc.

It appears that soluble starch is the glove powder of choice at the present time. Gloves should be washed or wiped off before hands are put into the peritoneal cavity and care should be taken to avoid spillage of glove powder, should a glove be torn during an operation.

The gross appearance of these granulomatous lesions ranges from a studding of the serous membranes with nodules resembling tubercles or larger masses, to the formation of dense fibrous adhesions.

Microscopically, the reaction is seen to be the formation of a chronic granuloma. There may be monocytes, epithelioid cells, multinucleated giant cells, lymphocytes, plasma cells, fibroblasts and sometimes areas of necrosis. Particles of the particular foreign material responsible can often be identified in the monocytes or giant cells by its characteristic appearance. Starch granules can be differentiated from talc by their blue staining with Gram's iodine and by formation of "Maltese crosses" when viewed with polarized light.

INTRAPERITONEAL ABSCESSES

An intraperitoneal abscess may be regarded as a complication or sequel of either localized or generalized peritonitis. If the peritoneum succeeds in completely walling off the infectious process but is not able to overcome the infection, an abscess develops. The situation may be looked upon as a stalemate between host and pathogen. However, the patient may be very ill from the infection and the presence of the abscess constitutes a constant threat to the life of the individual.

An intraperitoneal abscess may arise in one of two ways. First, it may result from a slowly advancing inflammatory process within the abdomen, in which case the abscess will develop in the immediate vicinity of the diseased organ, because the defenses of the peritoneum have had sufficient time to localize the infection. An appendiceal abscess is the most common example of this variety, but much the same process may occur from an acutely inflamed gallbladder with perforation, from acute diverticulitis, from hemorrhagic pancreatitis, from acute salpingitis and numerous other conditions which give rise, as a rule, to localized rather

than generalized peritonitis. In the second group there is usually sudden massive contamination of the entire peritoneal cavity, as in a perforated peptic ulcer or a penetrating wound with injury to bowel, in which, if the patient survives, the infection becomes secondarily localized. Such localization generally occurs in dependent parts of the abdominal cavity, to which the infected exudate tends to gravitate. These abscesses usually occur in the pelvis, and this is a favorable location, or in the subphrenic region, which is a very undesirable site.

Periappendiceal Abscess. Most periappendiceal abscesses lie in the right iliac fossa, but, largely because of the variable position of the appendix, the abscess may be pelvic, may lie in the paracolic gutter, may be in front of or behind the distal ileum or may be retroperitoneal in position. The postappendectomy abscess may also involve the operative wound.

An abscess need not arise from perforation of an organ. Infection may pass through the inflamed but intact wall as is usually the case with peridiverticular abscess. In the case of appendicitis, however, perforation usually has occurred by the time an abscess is diagnosed. As a result of inflammation and exudation of fibrin, omentum, mesentery and bowel become adherent about the appendix and localize the infection. There is no sharp demarcation between localized peritonitis and abscess formation—the exudate becomes progressively more purulent and the fibrinous adhesions become organized and within five to ten days an abscess has developed.

The pus of a periappendiceal abscess is never sterile. The organisms are those found in peritonitis, with *Escherichia coli*, streptococci, and staphylococci predominating. Mixed infections are not uncommon.

The symptoms of a periappendiceal abscess immediately follow and cannot be sharply distinguished from those of the preceding appendicitis and localized peritonitis. When a suppurative or gangrenous appendix has been removed, perhaps with some contamination at the time of surgery, there may be an interval of several days before the clinical features of an abscess are noted. If the infection has been suppressed by antibiotics the abscess may not be apparent for several weeks or even several months.

The patient with a periappendiceal abscess usually presents with spiking fever, abdominal pain and malaise. Following appendectomy there may be an apparently

cesses in the lesser sac are comparatively rare and are sealed off by adhesions about the foramen of Winslow.

Incidence. Subphrenic abscess is relatively uncommon. It is more often found in males than females (3:1), correlating with the higher incidence of primary etiologic lesions in males. In the first quarter of the present century the disease was more common in the second through the fourth decades, whereas it is now more common in the fifth and sixth decades of life. This may reflect earlier and better treatment of acute appendicitis and other abdominal emergencies and an increasing number of elective operations on the gastrointestinal tract of older patients.

Etiology. Subphrenic abscess is usually a sequel to abdominal surgery and to suppurative and perforative intra-abdominal lesions. At one time surgery was not a common cause, but elective operations now precede almost half the cases. Over half of the remainder follow appendicitis, perforated peptic ulcer and suppurative disease of the biliary tract. Occasionally it follows pancreatitis. Only 10 per cent of cases arise outside of the abdomen.

The infection either originates in the subphrenic region or it begins elsewhere in the abdomen and reaches the subphrenic region by spread of contamination over the peritoneal surface. Subphrenic abscess occasionally arises by hematogenous or lymphatic dissemination, by rupture of a liver abscess or by spread from a retroperitoneal phlegmon.

The organisms are the pyogenic bacteria which cause peritonitis—chiefly coliforms, streptococci and staphylococci. Tubercle bacilli are rarely the etiologic agent today. Occasionally in the southern United States subphrenic abscess is due to *Entamoeba histolytica*.

Pathology. Subphrenic contamination is often overcome by the peritoneum with or without the aid of antibiotics. It has been estimated that only 30 per cent of subphrenic infections go on to suppuration.

Subphrenic abscess is found on the right side far more often (75 per cent) than on the left. Gas is present in 25 per cent of subphrenic abscesses. It results from the pneumoperitoneum following perforation of bowel, as a sequel to surgery or from gas-forming organisms.

Most complications of subphrenic abscess are thoracic and the most common is pleural effusion. Other complications include pneu-

Figures 27 and 28 Diagrammatic representations of parasagittal sections, showing the subphrenic spaces on the right and left, respectively.

Figure 27. Subphrenic spaces on the right side. Note that the right posterior-superior space is really a recess arising from the right subhepatic space.

Figure 28 Subphrenic spaces on the left side. The left posterior-inferior space is the lesser peritoneal sac.

monitis, empyema, bronchopleural fistula, lung abscess, perforation of the diaphragm, pericarditis, perforation into a hollow abdominal viscus, spontaneous drainage to the outside, generalized peritonitis and hepatic suppuration. Occasionally, death may supervene without complications. Complications are the result of delayed diagnosis and treatment and markedly influence the prognosis. The mortality is three times as high when thoracic complications have been allowed to develop as when they are absent.

Clinical picture. The length of time that may elapse between operation or the onset of the primary disease, on the one hand, and the time the diagnosis is made, on the other, varies from a few days to over a year and the average is five months. A long latent period has always characterized a number of subphrenic abscesses but has been noted in an increasing proportion of cases since the introduction of antibiotics.

The onset of clinical symptoms may be abrupt, insidious or may blend imperceptibly with the initiating intra-abdominal infection.

nose and treat and because the life of the patient may depend upon adequate management. Untreated, they carry a 90 per cent mortality. Improperly treated, that is drained through the pleural or peritoneal cavity, the mortality rate is 35 per cent to 40 per cent. Early diagnosis and proper treatment reduce the mortality rate to approximately 10 per cent.

Anatomy. The location of a subphrenic abscess influences the clinical picture and the surgical approach indicated to provide drainage. The subphrenic region is subdivided into various spaces. A subphrenic abscess, because it is walled off by inflammatory adhesions, may not exactly coincide with the space in which it is situated. As a

rule, an abscess is found to occupy only one subphrenic space. When the right posterior superior space is involved, however, the right subhepatic space is frequently involved by an extension of the process.

There are six intraperitoneal subphrenic spaces or potential spaces. The liver conveniently divides the subphrenic compartment into suprahepatic and subhepatic areas, and the falciform ligament and ligamentum venosum demarcate the right and left sides (Figs. 20, 21, 25 and 26). There are three spaces above the liver and three below, there are three on the right and three on the left:

Figures 25 and 26: Views of the superior and inferior surfaces of the liver, showing the ligaments attached to it and the potential subphrenic spaces demarcated by the liver and its ligaments

Figure 25 Superior surface of liver showing the right anterior-superior and the left suprahepatic spaces of the subphrenic compartment. Compare with Figure 20.

Figure 26. Inferior surface of the same liver, which has been rotated upward 150 degrees. Compare with Figure 21.

On the right side there are two suprahepatic spaces and one subhepatic space (Fig. 27). The right anterior-superior space is a large space between the right lobe of the liver and diaphragm which is limited posteriorly by the anterior leaf of the coronary ligament and which communicates with the general peritoneal cavity anteriorly *over the free edge of the liver*. The right posterior-superior space is a small recess bounded by diaphragm, liver and posterior leaf of coronary ligament. This right posterior-superior space is really an upward extension of the right subhepatic space. The reason for designating the right posterior-superior space as a separate subphrenic space is that it is the site of a subphrenic abscess more often than any other. Exudate from the right paracolic gutter drains to this area in a recumbent patient. The right subhepatic space corresponds to the hepatorenal pouch of Morison.

On the left side, there is only one suprahepatic space but two subhepatic spaces (Fig. 28). The left suprahepatic space lies between the left lobe of the liver and the diaphragm and is bounded posteriorly by the left triangular ligament. Anteriorly this space communicates over the liver edge with the left anterior-inferior space. The left anterior inferior space lies below the left lobe of the liver in front of the gastrohepatic ligament, stomach and gastrocolic ligament, and it is sometimes designated the "perigastric space." The left posterior-inferior space corresponds to the lesser sac.

have been carried out, there is still doubt about the presence of a subphrenic abscess, surgical exploration may be necessary as an ultimate diagnostic procedure. Aspiration is not a permissible diagnostic or therapeutic procedure.

Prophylaxis. Measures for prevention of subphrenic abscesses are identical with those carried out in the prevention and treatment of peritonitis. Of particular importance

is positioning of the patient so that infective exudate drains toward the pelvis and away from the subphrenic area.

Treatment. The treatment consists of both supportive measures and surgical drainage. It is *absolutely essential that drainage be carried out by a route that avoids contamination of the unprotected pleural or peritoneal cavities.* For abscess of the posterior-superior and subhepatic spaces on the right side, the "extraserous route" of Ochsner and Nather, through the bed of the twelfth rib, is employed. Although it is true that one actually goes through peritoneum to drain the subhepatic abscess, the suppurative process is walled off anteriorly and there is no general dissemination of infection. For the right anterior-superior and left suprahepatic spaces, the anterior incision of Clairmont and Meyer, along the costal margin, is used. Left anterior-inferior and left posterior-inferior space infections are sufficiently well walled off by omentum and transverse colon that they may be drained by cautious approach through the anterior abdominal wall.

After free drainage has been established, several soft rubber drains are put into the depth of the cavity and are slowly withdrawn over a period of several weeks. If fever does not subside rapidly after drainage, serious consideration of the possibility of a second subphrenic abscess is indicated and appropriate investigation initiated.

ADHESIONS AND BANDS

Adhesions are abnormal attachments between peritoneal surfaces; they may be either fibrinous or fibrous. A band is a long, narrow, fibrous adhesion.

Etiology. Most adhesions are inflammatory in origin and follow either a surgical operation or peritonitis. Some adhesions are thought to be congenital. Others are due to mechanical violence and foreign bodies, but for the most part they may be considered to be inflammatory.

The amount of fibrin produced from the inflamed mesothelial surface of the peritoneum varies according to the chemical irritant or the microorganisms involved. If the action of the irritant is of only a few days' duration, the fibrin is usually absorbed. Intact mesothelium is necessary for resorption of fibrin. If the fibrinous adhesions are not absorbed for any reason, they are invaded by fibroblasts and capillaries and organization begins between five and ten days after the initial insult.

Factors favoring the development of

Figures 29 and 30: Posteroanterior and lateral x-rays of chest. The patient has a subphrenic abscess involving the right anterior-superior space. The films are unusual in that one seldom sees the typical features quite so well demonstrated.

Figure 29. Posteroanterior view. Note the elevation and thickening of the right hemidiaphragm and the presence of an air-fluid level beneath it.

Figure 30. Lateral view. The same three diagnostic features are seen.

Any abscess produces two groups of manifestations. (1) the systemic indications of suppuration, (2) the symptoms and signs which are peculiar to the location of the abscess. The inaccessible and deep-seated location of subphrenic abscess results in the localizing manifestations becoming apparent late in the course of the disease. Typically, subphrenic abscess is characterized early by systemic evidences of an abscess and little to indicate its location. Maingot quotes Barnard in the well-known axiom. "Signs of pus somewhere, signs of pus nowhere, signs of pus there." At the present time the problem of diagnosis is often made still more difficult by the use of antibiotics.* These agents may suppress for a time the systemic manifestations of the disease while the attenuated pathologic process slowly progresses.

The systemic manifestations of an untreated subphrenic abscess are those of any suppurative process. spiking fever, chills, rapid pulse, dehydration, toxæmia, and leukocytosis. If the infection has been masked by antibiotics, there may be little or no fever and only such nonspecific symptoms as weakness, malaise, anorexia and, as Blades has expressed it, "a lack of a sense of well-being." It is apparent that if antibiotics are being administered, minimal systemic symptomatology calls for a thorough inquiry and examination for local symptoms and signs.

The most important of the local symptoms is pain, which is usually present but which varies greatly in intensity. The pain is felt in the upper abdomen, along the costal margin, in the flank and renal region, or in the neck or shoulder. The site of pain is of some localizing value. Pain is aggravated by deep inspiration or movements of the trunk. In addition, there may be hiccups, cough or dyspnea.

The most consistent and valuable of the local physical findings is tenderness, the location of which may suggest the site of the abscess. There may be tenderness over the twelfth rib posteriorly with a posterior-su-

perior space abscess, tenderness along the costal margin in an anterior-superior space infection and tenderness with muscle guarding over the upper rectus in a subhepatic space abscess. Tenderness between the two heads of the sternocleidomastoid muscle due to irritation of the phrenic nerve has been described. There may be limitation of respiratory excursion, findings of pleural effusion, elevation and limited movement of a hemidiaphragm or crepitations in a lung base. Occasionally four distinct levels can be percussed: resonance (normal lung), dullness (pleural effusion), resonance (gas in abscess) and dullness (fluid of abscess and liver). In suprahepatic infections the liver will be displaced downward.

Minimal clinical suspicion demands preliminary x-ray studies. If fluoroscopy or chest films in full inspiration and full expiration show elevation, limited movement or thickening of a hemidiaphragm or pleural effusion, a full-scale radiologic investigation is necessary (Figs. 29 and 30). This includes planigrams and views in several positions with a horizontal x-ray beam in an attempt to demonstrate an air-fluid level and to try to distinguish elevated diaphragm from pleural fluid. If these studies are unrewarding, they may have to be repeated, because it is absolutely essential to establish the diagnosis and highly desirable to determine the location, should a subphrenic abscess exist.

Diagnosis. The first requisite for early diagnosis is awareness of the disease. The very obvious systemic manifestations without other apparent cause demand a searching investigation for physical signs and radiologic evidences of subphrenic abscess. If antibiotics are being administered, a still higher index of suspicion is necessary. If a patient has recently undergone surgery or has had an intra-abdominal infection and has only minimal symptoms under antibiotic cover, physical and radiologic examination is warranted. If no evidence of subphrenic abscess is found at this point, antibiotic therapy should be discontinued and the disease allowed to declare itself. A swinging fever and other full-blown systemic manifestations, as well as localizing symptoms and signs, will soon become apparent if the vague symptoms have been due to a suppressed subphrenic infection. It is better to allow the disease to become manifest and then proceed with proper therapy than to allow the masked process to progress.

If, after all other investigative measures

* The administration of antibiotics to treat a fever of undetermined origin is wrong in principle. When a patient develops a fever five to ten days after operation or intra-abdominal infection, however, and conscientious investigation reveals no cause, giving antibiotics for a few days is reasonable and justified. No doubt this practice aborts many subphrenic infections, although some progress to suppuration despite the drugs. The physician must appreciate that he is increasing his responsibility to detect lesions which may be masked by the drugs when he elects such a course.

formed the thirty-first operation for adhesions. This series of successive operations may last, as Hertzler stated, "as long as the patient does, or the hopeful persistence of the surgeon endures." The most satisfactory solution to this problem is to recognize that a patient of this kind will inevitably re-form adhesions and to replace haphazard adhesions with an organized pattern of non-obstructing adhesions such as one obtains with the Noble plication procedure.

INTRA-ABDOMINAL TRAUMA

Abdominal injuries, like peritonitis, have afflicted mankind from the remote past to the present day. It is a sad reflection upon our species that an undue proportion of these have been sustained in warfare* and today a very large number of abdominal injuries result from automobile accidents. Abdominal trauma makes up approximately 10 per cent of incapacitating injuries.

Injuries to the abdomen may be divided into two groups: *penetrating* and *nonpenetrating*, the latter being more common. These may be subdivided into injuries of solid or hollow viscera.

All types of abdominal trauma, penetrating or nonpenetrating, and regardless of the organ injured, may produce two effects—shock and peritonitis—singly or together. At the present time one-half to two-thirds of deaths from abdominal injuries are due to shock. Modern methods of treating peritonitis have greatly reduced the mortality from this complication.

PENETRATING INJURIES

A penetrating wound is one in which a foreign body has entered or traversed the abdominal cavity.

Penetrating injuries of the abdomen are usually produced by weapons and are important in military surgery. They are by no means rare among civilians. Loria states that the Charity Hospital in New Orleans, in a fifteen-year period, admitted over 800 such patients, about 60 per cent of the injuries were due to firearms and most of the remainder to various types of sharp instruments.

Wounds of the abdominal wall should be considered penetrating until proved otherwise. An external wound of the chest, back, buttock or perineum, in fact any wound from the shoulders to the knees, may penetrate the abdominal cavity.

* Loria states that the Ionian Greek word for physician, *iatros*, means "an extractor of arrows"

If there are wounds of entry and exit, the path of the blade or missile, unless it has been deflected by bone, may be plotted as a straight line; this is of some value in determining the probability of injury to the fixed organs. Any penetrating wound of the abdomen must be assumed to have perforated bowel wall, unless there is very good evidence to the contrary.

The organ most frequently injured is small intestine. Less frequently there is injury to liver, spleen, large bowel, stomach, mesenteries and major vessels. Several abdominal organs may be injured and there may be associated injuries, often of the thorax or urinary system. Trauma to multiple organs markedly increases the mortality.

The history should include information on the type of weapon and the position of the patient when wounded. The patient's symptoms (e.g., shoulder tip pain) will be of some value in diagnosing and localizing injuries, but one should not attach too much importance to the patient's denial of symptoms, especially if he is in shock or has multiple injuries. Often by the time a patient complains of symptoms, much valuable time has been lost.

Physical examination yields more information than does the history. The circulatory status, the blood pressure and the pulse, and their response following treatment, are of the utmost importance in determining the presence of continued bleeding. Shock is to be expected, but if ordinary resuscitative measures restore pulse and blood pressure to normal and these remain stable, one may assume that there is no continuing hemorrhage.

The appearance of the wound may be deceptive. A small wound may be the only visual evidence of an underlying potentially lethal injury.

The most reliable evidence of injury to a hollow viscus, according to Rob, is the absence of bowel sounds. If they remain absent for over an hour, abdominal exploration is mandatory. Abdominal tenderness and guarding may be present with either intraperitoneal blood or injury to a hollow viscus. Rectal examination should be carried out and it should be ascertained that the patient can pass urine normally. Stool and urine should be checked for blood.

If there is any likelihood of a kidney injury, an intravenous pyelogram should be obtained early. The kidneys will usually excrete the dye even in the presence of moderate shock. This is essential not only to

fibrous adhesions following chemical or bacterial peritonitis include: (1) continuing action of the irritant, (2) necrosis of the mesothelium due to intense action of the irritant, (3) a predisposition in certain individuals which is not well understood.

A surgical operation promotes fibrinous exudation by mechanical factors, i.e., handling viscera, sponges, instruments, foreign bodies, blood and, in some cases, low-grade and unsuspected infection. Fibrinous adhesions become fibrous in postoperative patients for the same reasons that they do in postperitonitic patients, but in the former there may be an additional factor of denudation of mesothelium—areas which are not adequately reepithelialized at the conclusion of operation. Fortunately, even fibrous adhesions may become attenuated and disappear in time.

Formation of adhesions is a protective process, without which irritants could not be localized and abdominal surgery would be impossible. These beneficial effects should be considered before attempts are made to abolish adhesion formation by means of drugs and chemicals.

Pathology. The chief complication of adhesions and bands is intestinal obstruction. At the present time this lesion has displaced external hernia as the most common single cause of mechanical intestinal obstruction. The adhesions and bands may involve intestine, mesentery, parietes, omentum or any other abdominal structure. They are usually fibrous by the time they give rise to obstruction. Small bowel is most often obstructed, usually the distal ileum. This is probably because more inflammations and operations occur in the right lower quadrant than in any other location.

Adhesions and bands obstruct the bowel by several mechanisms. Adhesions, by contraction of the fibrous tissue, may kink, compress or otherwise distort the bowel to cause a nonstrangulating obstruction. A pocket may form into which bowel prolapses or a narrow aperture may be produced through which a loop of bowel may herniate. A band may also serve as a pivot point for a volvulus.

Mechanical bowel obstruction due to fibrinous adhesions is relatively uncommon and usually occurs during the first week or ten days after operation or peritonitis.

Clinical Picture. Adhesions may produce symptoms other than those of intestinal obstruction, but this happens rarely and such a diagnosis should be made with reserva-

tions. The great majority of patients present with a mechanical small bowel obstruction and "a scar on the belly." The obstruction may be strangulating or nonstrangulating, a differentiation which frequently cannot be made with assurance on clinical grounds.

Prevention. There is no reliable way by which the formation of adhesions can be prevented, even if it were desirable to do so. The most a surgeon can hope to accomplish is the reduction of adhesion formation to a minimum. Of all the methods that have been tried to minimize adhesions, nothing has been shown to be as worth-while as careful attention to the details of surgical technique.

The points of surgical technique that are usually effective in reducing the number of adhesions are. (1) all denuded areas should be reepithelialized, (2) attention should be paid to hemostasis and blood should be evacuated from the peritoneal cavity at the end of the operation, (3) tissues should be handled gently, (4) warm, moist sponges and padded retractors should be used, (5) preoperative bowel preparation by mechanical cleansing and enteric antibiotics and sulfonamides before intestinal surgery is helpful, (6) the area about an open viscus should be packed off and spillage should be avoided, (7) drains should be used where indicated but should be removed as soon as it is safe to do so; (8) local use of sulfonamides and antibiotics has no advantage over systemic administration and these chemicals may act as foreign bodies and irritants.

Treatment. When a mechanical small bowel obstruction develops within a week or ten days after surgery, or after peritonitis without surgical operation, and one believes that the obstruction is due to fibrous adhesions, the patient may be treated with supportive measures and a long intestinal tube. The patient must be watched carefully and, if there is no response to this management, operative intervention may be necessary. As a rule the tube will pass through the small bowel and the obstruction will be relieved.

In cases of mechanical small bowel obstruction due to fibrous adhesions, the patient will come to surgery. Supportive measures and the use of the long tube are part of the preoperative preparation and not a substitute for operation.

In patients with a predisposition to form adhesions, ordinary methods of prophylaxis and treatment will prove futile. Wangenstein writes of one such patient on whom he per-

formed the thirty-first operation for adhesions. This series of successive operations may last, as Hertzler stated, "as long as the patient does, or the hopeful persistence of the surgeon endures." The most satisfactory solution to this problem is to recognize that a patient of this kind will inevitably re-form adhesions and to replace haphazard adhesions with an organized pattern of non-obstructing adhesions such as one obtains with the Noble plication procedure.

INTRA-ABDOMINAL TRAUMA

Abdominal injuries, like peritonitis, have afflicted mankind from the remote past to the present day. It is a sad reflection upon our species that an undue proportion of these have been sustained in warfare* and today a very large number of abdominal injuries result from automobile accidents. Abdominal trauma makes up approximately 10 per cent of incapacitating injuries.

Injuries to the abdomen may be divided into two groups: *penetrating* and *nonpenetrating*, the latter being more common. These may be subdivided into injuries of solid or hollow viscera.

All types of abdominal trauma, penetrating or nonpenetrating, and regardless of the organ injured, may produce two effects—shock and peritonitis—singly or together. At the present time one-half to two-thirds of deaths from abdominal injuries are due to shock. Modern methods of treating peritonitis have greatly reduced the mortality from this complication.

PENETRATING INJURIES

A penetrating wound is one in which a foreign body has entered or traversed the abdominal cavity.

Penetrating injuries of the abdomen are usually produced by weapons and are important in military surgery. They are by no means rare among civilians. Loria states that the Charity Hospital in New Orleans, in a fifteen-year period, admitted over 800 such patients, about 60 per cent of the injuries were due to firearms and most of the remainder to various types of sharp instruments.

Wounds of the abdominal wall should be considered penetrating until proved otherwise. An external wound of the chest, back, buttock or perineum, in fact any wound from the shoulders to the knees, may penetrate the abdominal cavity.

* Loria states that the Ionian Greek word for physician, *iatros*, means "an extractor of arrows."

If there are wounds of entry and exit, the path of the blade or missile, unless it has been deflected by bone, may be plotted as a straight line, this is of some value in determining the probability of injury to the fixed organs. Any penetrating wound of the abdomen must be assumed to have perforated bowel wall, unless there is very good evidence to the contrary.

The organ most frequently injured is small intestine. Less frequently there is injury to liver, spleen, large bowel, stomach, mesenteries and major vessels. Several abdominal organs may be injured and there may be associated injuries, often of the thorax or urinary system. Trauma to multiple organs markedly increases the mortality.

The history should include information on the type of weapon and the position of the patient when wounded. The patient's symptoms (e.g., shoulder tip pain) will be of some value in diagnosing and localizing injuries, but one should not attach too much importance to the patient's denial of symptoms, especially if he is in shock or has multiple injuries. Often by the time a patient complains of symptoms, much valuable time has been lost.

Physical examination yields more information than does the history. The circulatory status, the blood pressure and the pulse, and their response following treatment, are of the utmost importance in determining the presence of continued bleeding. Shock is to be expected, but if ordinary resuscitative measures restore pulse and blood pressure to normal and these remain stable, one may assume that there is no continuing hemorrhage.

The appearance of the wound may be deceptive. A small wound may be the only visual evidence of an underlying potentially lethal injury.

The most reliable evidence of injury to a hollow viscus, according to Rob, is the absence of bowel sounds. If they remain absent for over an hour, abdominal exploration is mandatory. Abdominal tenderness and guarding may be present with either intraperitoneal blood or injury to a hollow viscus. Rectal examination should be carried out and it should be ascertained that the patient can pass urine normally. Stool and urine should be checked for blood.

If there is any likelihood of a kidney injury, an intravenous pyelogram should be obtained early. The kidneys will usually excrete the dye even in the presence of moderate shock. This is essential not only to es-

tablish whether a kidney has been injured, but also whether the opposite kidney is functioning normally. Similarly, if there is any possibility of a bladder injury, there is only one reliable diagnostic procedure: cystography following instillation of 250 cc of radiopaque dye, 5 per cent sodium iodide.

A chest film and plain supine and upright (or left lateral decubitus) films of the abdomen should be taken to search for free intraperitoneal and retroperitoneal gas, muscle fragments, ileus and evidence of fluid.

The supportive treatment will often be initiated even before preliminary assessment of the patient is completed. Blood is drawn for crossmatching, even if there is no immediate intention of giving a transfusion. Intravenous fluids are started through a large needle or cut-down. A Levin tube of generous diameter is placed in the stomach for decompression. In the shocked patient urinary output as measured by a Foley catheter in the bladder is often a useful guide to the quantity of intravenous fluid required. A penetrating wound of the abdomen is one of the few instances in which prophylactic administration of antibiotics is justified. Narcotics are not administered to the patient with abdominal trauma until the surgeon responsible for the case has had an opportunity to examine the patient and has made a decision regarding operative intervention.

The patient with a penetrating injury to the abdomen will almost always require exploration. In this regard, Sir Gordon Gordon-Taylor states: "A penetrating wound in the abdomen probably means a penetrating wound of the bowel or other abdominal viscus and demands the earliest surgical intervention, unless a wisdom of prescience born of great experience justifies restraint." The only two instances when laparotomy may be deferred are: (1) when a patient is moribund, (2) in the occasional instance in which thorough and repeated examination of the patient reveals no abnormality whatsoever.

Usually a patient should not be taken to the operating room until he has been resuscitated and his pulse and blood pressure are stabilized (e.g. to the table tilt test). There are times, when a patient is actively bleeding as fast as one can pump blood into him, in which immediate intervention is indicated. If one is able to locate a controllable hemorrhage, the patient's condition will improve almost "miraculously" on the operating table.

When resuscitation may be carried out at a more leisurely pace, the outlook for the patient is improved, but operation should not be delayed beyond a few hours. Three factors influence the mortality: (1) the severity of the injury, (2) the duration of shock and (3) the duration of peritoneal contamination. The objectives of operation are to control bleeding and to prevent continuing contamination of the peritoneal cavity.

NONPENETRATING INJURIES

These are also known as closed or subcutaneous injuries, or injuries due to blunt trauma. They are more important than penetrating injuries because they are not only more common, but they are more difficult to manage, since clear-cut indications for operative intervention may be absent.

Approximately half of the serious nonpenetrating injuries to the abdomen which occur in North America are caused by automobile accidents. The steering wheel is a particularly dangerous instrument. Falls, athletic injuries, mining accidents and being struck by falling objects account for a certain number.

The forces that produce the injury to the abdominal contents are of four types: (1) an anterior-posterior or lateral squeezing force which crushes the viscus, usually against unyielding bone, (2) a tangential force which moves a viscus beyond the limits of its mobility with a tearing of its attachments or capsule, (3) a sudden compressing force which, in effect, bursts a hollow organ as if it were a paper bag, (4) a blasting force with widespread shattering of tissues with petechial hemorrhages.

Fixed organs are more likely to be injured than those which are more mobile. The organs injured, in approximate order of frequency, are liver, spleen, small bowel, large bowel, kidneys, stomach, bladder, diaphragm (left side) and, rarely, a pregnant uterus. The proximal jejunum and distal ileum are the parts of the small intestine most frequently injured (near points of fixation) and bowel is more often injured on its antimesenteric border. The same lesson may spill fecal material and bleed profusely. The vulnerable portion of the duodenum is the third part where it crosses the body of the third lumbar vertebra. A hollow viscus is always more susceptible to injury when distended than when empty.

The injuries frequently involve more than one organ, in which case the mortality rate

is increased from less than 10 per cent to more than 30 per cent. The lethal factors—shock and peritoneal contamination—frequently coexist in the same patient.

Delayed hemorrhage may occur. The most frequent type presents in delayed rupture of the spleen. This variety of injury occurs once in seven instances of splenic rupture. Delayed intra-abdominal hemorrhage may also result from injury to liver, to duodenum and pancreas and to kidney.

The difficult clinical problem in cases of blunt trauma to the abdomen is to establish the diagnosis of a potentially lethal injury sufficiently early to avoid the high mortality rate which results from prolonged contamination of the peritoneal cavity. A ruptured hollow viscus may produce few symptoms during the most favorable time for closure. The physical findings may be no more than could be explained on the basis of a small amount of blood in the peritoneal cavity or on the basis of a retroperitoneal hemorrhage. Routine operation is not a solution to this problem because a negative exploration also carries an increased mortality. The only answer is thorough initial investigation and frequent re-evaluation by the same surgeon.

The history may be very misleading. The initial trauma may be remarkably trivial. A history of a severe blow to the abdomen followed by rapid recovery and an interval of several hours without symptoms in no way rules out intra-abdominal injury. The nature and location of the blunt trauma will enable the physician to visualize the possible underlying injuries. The presence and location of pain are of some diagnostic value. A history of persistent vomiting is suggestive of bowel rupture, particularly if the vomitus is bloody. Difficulty in voiding or hematuria will direct attention to the urinary tract.

The history will only suggest the presence of a serious lesion, but this diagnosis must be made from the physical findings supported by laboratory aids, chiefly the x-ray films.

The patient with significant nonpenetrating trauma to the abdomen will usually be in shock on admission. Resuscitation with whole blood should be carried out concomitantly with the clinical assessment of the patient. Military experience in Korea has indicated that severely injured persons may require quantities of blood far in excess of the amount of blood lost from hemorrhage or the amount of fluid displaced into traumatized tissues. These resuscitative measures

are, in a sense, diagnostic as well as therapeutic. Failure of the patient to respond to liberal administration of whole blood or a temporary response to blood indicates either very severe trauma or continued hemorrhage.

One should search for an area of contusion on the abdominal wall. Tenderness, guarding and rebound tenderness are usually due to rupture of a hollow viscus but can be caused by blood in the peritoneal cavity. The absence of bowel sounds always suggests severe injury, but it is not by itself an absolute criterion for exploration, as paralytic ileus may be caused by a retroperitoneal hematoma. Obliteration of liver dullness is almost pathognomonic of rupture of some part of the gastrointestinal tract. Shifting dullness in the flanks and fluid in the cul-de-sac on rectal examination are occasionally noted.

Scout films of the abdomen and chest should be taken. Fractured lower ribs should alert one to the possibility of rupture of spleen or liver, but rib fractures are found in only 50 per cent of fatal cases. Finding of free gas on the upright or left lateral decubitus films will make exploration mandatory. A fracture of the pelvis in the vicinity of the pubic ramus which opens up the pelvic ring makes a cystogram absolutely indispensable. If there is any suspicion of kidney trauma, intravenous pyelography should be carried out early.

Peritoneal aspiration under local anesthesia is a useful diagnostic adjunct. The finding of blood, bile, fecal material or fluid with a high amylase content may influence the management.

Whether or not operation is indicated, a program of supportive therapy should be instituted.

The objectives of operation are the same for both penetrating and nonpenetrating trauma to the abdomen: control of hemorrhage and prevention of continued contamination of the peritoneal cavity. The treatment of bleeding from a ruptured spleen has high priority and the hemorrhage often becomes profuse when the abdomen is opened. Splenectomy is the only permissible procedure. The essential considerations in the treatment of liver injuries are: (1) to stop bleeding, (2) to excise devitalized fragments and (3) to drain. Bleeding may be controlled with mattress sutures and hemostatic sponges (Gelfoam and Oxycel); packs should not be used. Drainage is essential because bile leakage will occur and may

lead to fatal peritonitis. Trauma to the pancreas usually requires only drainage. An opening in the stomach may be treated by excision of wound edges and closure with sutures. The small bowel should be systematically inspected from the ligament of Treitz to the ileocecal valve, wounds are treated either by resection or by a method of suture that does not narrow the lumen. The anterior surface of the duodenum should be inspected for an intraperitoneal rupture, which can usually be closed with sutures. At the same time, one should be alert for bile-stained blood and gas behind the peritoneum, indicating a retroperitoneal rupture of the duodenum; this requires mobilization of the duodenum, suture and drainage. Openings in the large bowel beyond the hepatic flexure must either be exteriorized or sutured and protected with a proximal colostomy. It is not so important to protect a suture line in the cecum or ascending colon, but a catheter cecostomy is often useful. A wound of the gallbladder is treated by cholecystectomy. Injury to the common bile duct is treated by suture and T-tube drainage. Bladder wounds are closed, the usual care being exercised not to put chromic catgut or nonabsorbable sutures through the mucosa. A urethral catheter or suprapubic tube is inserted and the extraperitoneal tissues about the bladder are drained. Nephrectomy is seldom necessary unless the kidney is severely fragmented.

Postoperatively, the patient is maintained on supportive therapy until recovery is complete.

HEMOPERITONEUM

Hemoperitoneum may be either *traumatic* or *spontaneous*. The trauma may be trivial, especially if bleeding comes from a previously diseased organ. Delayed hemorrhage from nonpenetrating trauma to the abdomen may also occur.

The lesions which may cause spontaneous hemoperitoneum include ectopic pregnancy, blood dyscrasias, rupture of an artery which is the seat of a degenerative process, torsion of omentum, spleen, fibroid tumor or ovarian cyst, mesenteric vascular occlusion and pancreatitis.

The most probable source of a large amount of blood in the male is rupture of the spleen. In the female of childbearing age it is ectopic pregnancy.

Hemorrhage should be controlled and the blood evacuated. Blood in the peritoneal cavity is a much greater hazard to the pa-

tient than any possible benefit that might accrue from having this blood as a source of iron.

PNEUMOPERITONEUM

Pneumoperitoneum is the presence of gas within the peritoneal cavity. The detection of free intraperitoneal gas is of great value in the diagnosis of a perforated abdominal viscus. There are, however, other important causes of pneumoperitoneum which are included in the following etiologic classification:

CLASSIFICATION OF PNEUMOPERITONEUM

A. From Within the Lumen of the Gastrointestinal Tract

1. Perforated peptic ulcer
2. Other perforative disease
3. Blunt and penetrating trauma to the abdomen
4. Endoscopic instrumentation
5. Infections
6. Postanesthetic

B From Outside the Lumen of the Gastrointestinal Tract

1. Postoperative
2. Diagnostic
 - (a) Rubin Test
 - (b) Needle
3. Therapeutic
4. Penetrating trauma

C. Idiopathic

Perforated Viscus. Perforated peptic ulcer is the commonest disease process producing pneumoperitoneum. The demonstration of free intraperitoneal air in a patient with an "acute abdomen" usually indicates a perforation of the gastrointestinal tract.

Demonstrable pneumoperitoneum occurs with more than half of perforated peptic ulcers. The detection of air depends upon many factors, including (1) the time elapsed since perforation, (2) the location and size of the perforation, (3) the effectiveness of reaction in walling off the perforation, (4) the amount of air in the stomach at the time of perforation and (5) the amount swallowed subsequently.

Benign and malignant ulcerating lesions and obstructing lesions in which perforation of the gastrointestinal tract occasionally occurs may produce pneumoperitoneum.

Free gas in the peritoneal cavity seeks the highest level and, in the upright position, tends to accumulate under the diaphragm. Although absence of liver dullness in the midaxillary line is clinically indicative of

pneumoperitoneum, accurate detection requires careful radiologic examination (Figs. 31 and 32). A few cubic centimeters of air may be seen on a scout film of the abdomen if sufficient time is allowed for the gas to collect in whatever part of the cavity is uppermost. Erect and left lateral decubitus views are commonly used.

Traumatic. Pneumoperitoneum following blunt trauma to the abdomen indicates a perforated viscus. Pneumoperitoneum following a penetrating or perforating abdominal wound reveals only peritoneal entrance, since air may enter with the missile. Visceral involvement, however, is common if the peritoneum is entered and the detection of free intraperitoneal air is a positive indication for laparotomy.

Accidental. Instrumental visualization of abdominal organs, often accompanied by air insufflation, may perforate a normal or diseased viscus and produce pneumoperitoneum. Perforation during sigmoidoscopy under direct vision is rare. Pneumoperitoneum occasionally follows gastroscopy, but usually gross perforation is not found at laparotomy. In the absence of clinical peritonitis these patients have been successfully treated conservatively.

Infections. Certain gas-forming organisms may cause pneumoperitoneum in an intra-

abdominal abscess. *Clostridium coli*, anaerobic streptococci and *Proteus* have also occasionally been cultured. The formation of gas in an abdominal abscess may be a valuable aid in diagnosis and localization.

Postanesthetic. Pneumoperitoneum following surgery is occasionally related to anesthesia. Excessive airway pressure during assisted respiration, or rapid oxygen flow through a nasal catheter, may produce gastric dilatation and, rarely, gastric perforation. Intrapertoneal gas following anesthesia is not always associated with perforation or peritonitis; the gas may diffuse beneath the mucosa along the vessels of the stomach into the peritoneal cavity.

Postoperative. The most frequent cause of pneumoperitoneum is abdominal surgery. The peritoneal cavity is normally a potential space in which there is a negative pressure. When the peritoneum is opened at operation an inrush of air may be noted. The duration of postoperative pneumoperitoneum is variable; small quantities of air are usually absorbed within a few days. In the majority of patients the air has disappeared

by fourteen days, but rarely it may persist for as long as six weeks.

There is no apparent correlation between pneumoperitoneum and postoperative pulmonary complications. The presence of intraperitoneal air following surgery may

Figures 31 and 32: Posteroanterior and lateral x-rays of chest. The patient has a perforated peptic ulcer, the most common cause of pneumoperitoneum other than laparotomy:

Figure 31. Posteroanterior view, showing a thin rim of free air beneath both leaves of the diaphragm.

Figure 32. Lateral view, same patient. These films were taken in the upright position. If patient is too ill to be upright for a few minutes before films are taken, the left lateral decubitus position should be used, with patient lying on his left side.

confuse the assessment of postoperative abdominal complications.

Diagnostic. Direct injection of gas into the peritoneal cavity to outline the abdominal and pelvic organs has been used in selected cases as an aid in the radiologic diagnosis.

The potential communication between the peritoneal cavity and the exterior existing in the normal female via the fallopian tubes and the uterine cavity is utilized in the Rubin test.

Therapeutic. Artificial pneumoperitoneum has been used in the treatment of pulmonary and abdominal tuberculosis for many years. Five hundred to 1000 cc. of air or oxygen is injected directly into the peritoneal cavity with periodic refills. Elevation of the diaphragms with reduction of pulmonary volume tends to promote collapse of tuberculous cavities, particularly if they are located in the base of the lungs. This treatment often combined with phrenicectomy and chemotherapy is considered of value in some instances. Another use therapeutically is the preparation of the patient with a very large ventral hernia for operation. The air is introduced into the peritoneal cavity while the hernia is under control with strapping. This has been a very useful procedure in selected cases.

Idiopathic or Undetermined Cause. Spontaneous idiopathic pneumoperitoneum occurs rarely with no demonstrable perforation of a viscus, known exogenous cause or underlying disease process. It produces few clinical manifestations and usually subsides without ill effect.

TUMORS OF THE PERITONEUM

The great majority of peritoneal tumors are secondary. Primary tumors of the peritoneum or of any serous membrane are very rare.

PRIMARY TUMORS

Neoplasms may arise from any of the fibrous, fatty, vascular or reticular tissues which lie beneath the peritoneal mesothelium, but such are best regarded as tumors of the viscera, perietes or retroperitoneum. The tumor of mesothelium, the mesothelioma, is the only primary tumor of the peritoneum. Although it is very rare, most pathologists agree that the primary peritoneal mesothelioma is a recognizable entity. Both benign and malignant varieties of mesothelioma exist. The lesions may be localized or diffuse and they occur in plaque-like and nodular forms. The tumor may

spread over and encompass the viscera, producing fibrous thickening of the peritoneum and shortening of the mesentery. Intestinal obstruction, viscid ascites and obliteration of the peritoneal cavity have been reported. Even malignant forms do not invade until late and seldom metastasize.

The neoplasm may have the microscopic appearance of a papillary, fibrous, acinar or even squamous cell tumor. It is very difficult for the pathologist to establish the diagnosis on the basis of examination of ascitic fluid or a small amount of biopsy material.

The benign form, if localized, can be effectively treated by surgical excision.

SECONDARY TUMORS

The primary lesions are usually found in stomach, colon, ovary, uterus, breast, biliary system, pancreas, lung and lymph nodes. Most secondary tumors of the peritoneum are metastatic carcinomas. The malignant tumor reaches the peritoneal surface by permeation through the wall of a viscus, by hematogenous and lymphatic spread and occasionally by inoculation at the time of surgery. Once in the peritoneal cavity, tumor may be disseminated over the serosal surface.

The gross appearance of secondary tumors varies widely, according to the primary lesion and the mode of spread. The main features are ascites and tumor nodules. The ascitic fluid is usually bloody and often contains exfoliated tumor cells. The tumor ranges from minute deposits, a millimeter or less in diameter, studded diffusely over the peritoneal membrane, to large plaques and masses of neoplastic tissue. As a rule the tumor nodules are less than a centimeter in diameter. The omentum may be so infiltrated with tumor that it is converted into a hard mass. There may be "drop metastases" to the cul-de-sac, giving rise to a rectal shelf. Sometimes a reticular pattern of white lymphatics, permeated with tumor, is seen beneath serosa. It may be difficult to distinguish grossly the nodular lesions of secondary peritoneal tumor from those of tuberculosis, fat necrosis or foreign body granuloma.

Not all secondary tumors are malignant. One benign secondary lesion is the "parasitic fibroid," a leiomyoma that has become detached from the uterus and taken up a new attachment on the peritoneal surface. Similarly, dermoid cysts of the ovary sometimes become secondarily attached to peritoneum.

An interesting form of secondary tumor of the peritoneum is *pseudomyxoma peritonei*, which arises from rupture of a pseudomucinous cystadenoma of the ovary or rarely of the appendix. A lesion of similar appearance may be produced by rupture of a mucocele of the appendix, in which case the mucus acts as an irritant and produces chemical peritonitis. The mucus-producing cells become implanted on the peritoneum and continue to produce a gelatinous exudate causing the so-called jelly belly.

The patient with metastases to the peritoneum usually has advanced symptoms of the primary lesion. He may complain of pain, discomfort or cardiorespiratory symptoms from abdominal distention. Cachexia, pallor and ascites are often present when the patient is seen for the first time. One may palpate tumor tissue in the form of a primary lesion, a Virchow's node, liver nodules, an omental mass or a rectal shelf.

If there is no evidence of metastatic malignancy other than the ascites, abdominal fluid may be examined cytologically. This examination is subject to the limitations inherent in the cytologic method.

Treatment can only be symptomatic. Abdominal tapping may be done for the comfort of the patient. Instillation of colloidal Au¹⁹⁹ or radiomimetic drugs may reduce ascites when the tumor nodules are only a few millimeters in diameter and there is no block at the porta hepatis.

MESENTERIES AND OMENTUM ANATOMY AND PHYSIOLOGY

The stomach, jejunum, ileum, appendix, transverse colon, sigmoid colon, liver and spleen are attached to the posterior wall of the abdominal cavity by mesenteries, which carry their respective blood vessels, lymphatics and lymph nodes. The gastrohepatic ligament is the ventral mesentery of the stomach and first part of the duodenum, but it is also, in a sense, a dorsal mesentery of the liver and gallbladder. The gastrocolic ligament is continuous with the anterior layer of the greater omentum. The mesentery of the jejunum is described as fan shaped, averaging 12 to 25 cm. in height. Its junction with parietal peritoneum is only 15 cm. long, whereas its other border, where it enfolds small bowel, is about 700 cm. in length. This marked disparity in the lengths of its two borders can only be reconciled by numerous folds toward the enteric border. All mesenteries consist of two layers of

mesothelium enclosing a variable amount of fatty and loose connective tissue, vessels and lymph nodes.

The mesenteries of the duodenum, pancreas, ascending colon and descending colon have disappeared in fetal life because of fusion with parietal peritoneum. Fortunately for the surgeon, these planes of fusion can usually be converted into planes of cleavage, restoring the primitive state. The "mesentery" thus created has only one layer of mesothelium, the posterior parietal peritoneum, but it carries in its fatty areolar tissue the blood vessels, lymphatics and lymph nodes of the organ in question.

The greater omentum is a double fold of mesentery embryologically. One might expect it to contain four mesothelial layers, but the central two have fused and vanished. The size and fat content of the greater omentum are highly variable. Its role as the "abdominal policeman" seems well supported by experimental and clinical evidence. The areolar tissue of the omentum is rich in macrophages. Bacteria or carbon particles injected into the peritoneal cavity are rapidly removed by the omentum and are subsequently seen to be situated in phagocytes beneath its mesothelium. The ability of the omentum to adhere to sites of inflammation and perforation has been mentioned in the discussion of peritonitis. Foreign bodies in the peritoneal cavity, such as a bullet or a sponge, are often found completely wrapped in omentum.

The presence of the greater omentum is not always beneficial. Adhesions and bands between the omentum and either parietes or viscera, or openings made in the omentum at surgical operations, may lead to intestinal obstruction. Once a patient has had some such difficulty originating in the omentum, surgical excision of the omentum will circumvent further complications.

MESENTERIC LYMPHADENITIS ACUTE NONSPECIFIC MESENTERIC LYMPHADENITIS

Over the past thirty years this disease has been delineated from tuberculous lymphadenitis and has gradually gained wide acceptance as a clinical entity. Its chief importance lies in the fact that it produces the picture of an "acute abdomen" and must be considered in the differential diagnosis of appendicitis.

Acute nonspecific mesenteric lymphadenitis is uncommon and in our experience the

incidence is diminishing. Most patients are between five and fifteen years of age and it is somewhat more frequent in boys.

The etiology is unknown and there may be more than one cause. Cultures from the enlarged mesenteric lymph nodes are usually negative. Associated low-grade inflammatory changes in the appendix and distal ileum have been reported in a large proportion of cases and may have a bearing on the etiology.

The appendix is grossly normal. There is discrete enlargement of the mesenteric lymph nodes in the ileocecal angle, particularly those in the juxtaintestinal group. Lymph nodes in this region are prominent in children and normal lymph nodes must be distinguished from those which are pathologic. The nodes vary from soft and pink in the early stage of the disease to firm and white later. Microscopically, the lymph nodes show only nonspecific changes: hyperplasia, edema and hyperemia.

The child with acute nonspecific mesenteric lymphadenitis usually presents with colicky abdominal pain vaguely situated about the umbilicus, right side or right lower quadrant. The pain is of variable intensity, but in the course of the cramps the child feels fairly well. There is often a recent upper respiratory infection, which may still be present. There is a history of previous attacks, separated by intervals of several months, in over half the cases. Malaise, anorexia, nausea or vomiting is also frequently present or reported in earlier attacks.

The child does not look or act ill. There is fever, usually under 100° F. The patient is flushed and there may be circumoral pallor. The pharynx is often injected and the cervical lymph nodes may be enlarged. Abdominal tenderness is higher, more medial, less well localized and more variable from one time to another than in appendicitis. Shifting tenderness (i.e., shift of point of maximum tenderness to the left when child lies on left side), due to change in position of the mesentery and nodes, is said to be characteristic but is often absent. The white blood count may be increased to 10,000 to 15,000 per cu. mm.

Indiscriminate appendectomy cannot be condoned. However, if one suspects acute appendicitis the matter should be settled by laparotomy. On the other hand, if one can be reasonably confident of a diagnosis of mesenteric adenitis, a few hours of observation may be confirmatory. The signs and

symptoms of this latter disease will subside or improve in less than twenty-four hours.

If, at laparotomy, one finds a normal appendix and the characteristic lymphadenopathy in the ileocecal angle, appendectomy should be carried out. It is not advisable to remove a lymph node for biopsy, because bowel may become adherent to the site. Postoperative respiratory complications should be anticipated. A small proportion of these patients may have further attacks after appendectomy, but there is an over-all tendency toward recovery.

TUBERCULOUS MESENTERIC LYMPHADENITIS

Involvement of mesenteric lymph nodes by tubercle bacilli is now uncommon. The disease may be primary, in which case the organisms, usually bovine, gain entry through intact mucosa to Peyer's patches and then reach the nodes. The disease may be secondary to tuberculosis of lungs or bowel.

The pathologic picture is that of tuberculous lymphadenitis elsewhere, with tubercle formation, caseation and eventually calcification. The disease may be complicated by peritoneal adhesions, tuberculous peritonitis or secondary pyogenic infection.

The disease is seen in acute and chronic forms and its manifestations are highly variable. The salient features are fever, general ill health, weight loss, diarrhea and cramping abdominal pain.

X-ray of the abdomen in a clinically well person may show calcified lymph nodes in the right iliac fossa—the so-called chalky tombstones of tubercle bacilli, which may or may not be dead.

In general, the treatment should be conservative with antituberculous drugs and supportive measures.

MESENTERIC AND OMENTAL CYSTS

A variety of unusual cysts may be found in the mesenteries and omentum. These include: (1) enterogenous cysts or congenital reduplications, (2) lymphatic cysts, either cavernous lymphangiomas or cystic lymphangiectasis, (3) dermoid cysts, (4) hydatid cysts.

The cysts may produce no symptoms or only abdominal enlargement and vague discomfort. Occasionally a patient presents with intestinal hemorrhage or obstruction. Cysts of the omentum may give rise to secondary torsion and the clinical picture of an "acute abdomen." The characteristic physical finding is a "floating tumor." Cyst in the

mesentery have greater mobility from side to side than in a vertical direction.

If surgical intervention is necessary, the ideal treatment is to shell out the cyst. Unfortunately this is seldom possible in the mesentery, as vessels supplying the bowel are adherent to the cyst wall, and it may be necessary to resect bowel. A cyst of the omentum is easily treated by excision. Hydatid cyst may be treated by deep x-ray therapy or by excision with care not to spill the fluid, which would reinfect the patient or cause a severe anaphylactic reaction.

INFARCTION OF THE OMENTUM

Infarction of the greater omentum may be due to: (1) torsion, (2) thrombosis, (3) polyarteritis nodosa, (4) embolism, (5) trauma, (6) unknown etiology.

Idiopathic segmental infarction of the omentum is rare, reports of only forty cases having been published. It is most often found in well-nourished men in the third decade. The cause is obscure, but it is thought to be related to venous engorgement (sometimes seen after a full meal) and mild trauma or increase in intra-abdominal pressure, leading to thrombosis. Usually the right, lower, free margin of the omentum is infarcted.

Patients present with steady, severe right lower quadrant pain, the onset of which may be gradual or sudden. Nausea and vomiting are unusual. On examination, the tenderness is usually higher than one would expect for appendicitis and a mass may be palpable. Cutaneous hyperesthesia is said to be characteristic.

The correct diagnosis has never been made preoperatively, most cases are called acute appendicitis. The finding of a normal appendix and some serosanguineous fluid in the peritoneal cavity should always direct one's attention to disease elsewhere. The infarcted area forms a firm, red to purplish-black mass. Treatment is wide excision of the involved omentum.

TORSION OF THE OMENTUM

Torsion of the omentum may be classified as primary and secondary. Secondary torsion is more common and is subdivided into bipolar and unipolar types, depending on whether or not there is a secondary fixation of the omentum. Among the causes are hernias, adhesions, cysts and tumors.

In primary torsion of the omentum there is no apparent cause, although vigorous exercise, movement of the omentum by intes-

tinal peristalsis and hemodynamic forces have been blamed. The torsion is always unipolar and may be either complete or incomplete. In the complete type there may be up to six full turns. The omentum is usually quite large and fatty with a long pedicle and a narrow attachment. It is often the right, free margin of the omentum that is involved in the torsion.

The clinical picture and treatment of torsion of the omentum are similar to those of infarction of the omentum.

APPENDICES EPILOICAE

The appendices epiploicae are fat-laden pouches of peritoneum which are found on the large bowel and rarely on the appendix. They are usually arranged in two rows, one medial to the taenia libera and one lateral to the taenia omentalis. These are the sites at which some of the vessels enter the bowel wall. One will recall that diverticula also are situated in these positions.

The appendices epiploicae may be the sites of a number of diseases, the most common of which is "epiploic appendicitis." This may be due to torsion or thrombosis and so may be regarded as a miniature counterpart of torsion and infarction of the omentum. Epiploic appendicitis is found chiefly in the sigmoid and cecal regions. Other disease processes in which the appendices epiploicae may be involved include: (1) acute and chronic inflammation secondary to diverticulitis, (2) degeneration to form an intraperitoneal loose body, (3) initiation of an intussusception, (4) incarceration in a hernia.

The presenting symptom of epiploic appendicitis is lower abdominal pain on either the right or left side. The correct diagnosis is seldom made preoperatively. Treatment is excision with care not to open up a diverticulum.

RETROPERITONEAL SPACE

ANATOMY

The retroperitoneal space from the surgeon's viewpoint is a potential space extending from the respiratory diaphragm above to the pelvic diaphragm below. Its posterior boundaries are the vertebral bodies, the psoas and quadratus lumborum muscles and the aponeurotic portions of the transverse abdominis muscles (Fig. 23). Below the iliac crests it is bounded by the sacrum and the psoas and piriformis muscles posteriorly, and by the iliacus and obturatorius internus muscles laterally. The an-

terior boundary of the retroperitoneal space is chiefly the posterior parietal peritoneum, but in addition the anterior boundary is made up of the posterior surface of the liver, the ascending and descending portions of the large intestine, the retroperitoneal portion of the duodenum and the rectum.

The major organs of the retroperitoneal space are the kidneys and ureters, the adrenals and the pancreas. The space is also occupied by the great systemic vessels and their branches, veins of the portal system, lymphatic vessels and lymph nodes, somatic nerves, sympathetic chains and autonomic plexuses and an abundance of fatty and areolar connective tissue.

RETROPERITONEAL HEMORRHAGE

Bleeding into the retroperitoneal space is a sequel to blunt trauma to the trunk, fractures of the pelvis or lumbar vertebrae, especially of their transverse processes, and lacerations of the kidney. Because the blood is irritating to both somatic and autonomic nerves, the clinical picture of peritonitis may be simulated. There may be abdominal pain, nausea, vomiting, abdominal guarding, low-grade fever and leukocytosis. This syndrome may proceed to adynamic ileus characterized by a silent distended abdomen. Except for rupture of an aortic aneurysm and rare instances of severe trauma to the kidney or renal vessels, retroperitoneal bleeding seldom presents as an exsanguinating hemorrhage.

Retroperitoneal bleeding should be recognized early and the ileus and gastric dilatation treated by gastrointestinal decompression. The possibility of a more serious intra-abdominal lesion initially presenting with a similar clinical picture should be considered. The differential diagnosis is difficult and must occasionally be made at laparotomy.

RETROPERITONEAL TUMORS

It is customary to exclude tumors of the kidneys, ureters, adrenals, pancreas and bowel as well as metastatic tumors to the retroperitoneal lymph nodes from the group of neoplasms designated as retroperitoneal tumors.

The most common of the primary tumors seen in the retroperitoneal space are the lymphomas, i.e., lymphosarcoma, Hodgkin's disease and reticulum cell sarcoma. The second most common is the liposarcoma—a noteworthy oddity, since elsewhere in the body benign fatty tumors are quite common and malignant fatty tumors are almost un-

known. The remaining tumors are those which arise from the mesodermal tissues in the retroperitoneal space. The majority (50 per cent) are malignant, and one-third have metastasized at the time they are diagnosed. Those which are benign tend to recur after removal.

Because the retroperitoneum is a distensible space, these tumors may reach very large size before they are diagnosed. About half the patients present with pain and one-third with an abdominal mass. Gastrointestinal symptoms, backache, pain and swelling in a leg, genitourinary symptoms and fever are occasionally early symptoms.

The most common physical finding is a fixed or movable mass, usually nontender. Varicocele, edema or varicosities of a leg, a forward protrusion of the liver, lumbar dullness on percussion and occasionally a neurologic deficit, especially with dumbbell tumors, may be found.

The chief laboratory aid is the x-ray and the most important investigation is the pyelogram with anteroposterior and lateral views. The ureters, which are adherent to the posterior parietal peritoneum, are seen to be displaced forward or laterally. The function of each kidney should be assessed, as one kidney may need to be sacrificed at operation in order to encompass the lesion. The next most important radiologic procedure is a gastrointestinal series. Presacral oxygen insufflation may be useful to outline the contents of the retroperitoneal area. Aortography and venography may be useful, as the great vessels are often displaced.

At the time of operative intervention, most retroperitoneal tumors will have surrounded or invaded major organs and vessels. Curative surgery is possible in about 20 per cent and the operative mortality ranges from 10 to 25 per cent.

Operation is required to assess the tumor and establish a diagnosis. A proportion of the tumors are amenable to surgical treatment, but each case must be individually evaluated. Close cooperation between the surgeon and the pathologist is necessary in order to determine the curability of the lesion and the extent of surgical extirpation which is justified. It may be necessary to sacrifice one kidney or the vena cava below the renal veins. If complete excision is impossible, the residual tumors will be radio-sensitive to some degree in about three-quarters of the cases. These remaining patients should be treated with radiation or radiomimetic drugs.

HERNIA

By CHESTER B. McVAY, M.D.

CHESTER BIDWELL McVAY left Yankton, South Dakota, his birthplace, to receive his medical education, do graduate degree work in anatomy at Northwestern University and receive his surgical training at the University of Michigan. After military service in World War II, he returned to Yankton to practice and is Clinical Professor of Surgery and Associate Professor of Anatomy at the University of South Dakota. His union of anatomy and surgery has made him an authoritative and stimulating investigator of the surgical problems of hernia.

Historically, the development of hernia surgery is one of the most interesting chapters in the field of medicine, since hernias have always been the most common visible affliction of man amenable to surgical treatment. Its common occurrence and the enigma of its etiologic background and its cure through the ages have made the hernia story an absorbing narrative which has few peers even in the field of fiction. The story in the past seventy years is a monument to the surgeons' ingenuity, but the multiplicity of modern operations for inguinal and femoral hernias is a record of basic misunderstanding of the anatomy involved.

Definition. The classical definition of a hernia is "the protrusion of a viscus from its normal cavity through a congenital or an acquired aperture." While this definition suffices in a general way, it requires some elucidation. For example, a patient may have a hernia consisting entirely of preperitoneal fat, without a peritoneal sac and without the protrusion of a viscus. This is quite common in epigastric and femoral hernias in the early stages. Occasionally, in indirect inguinal hernias, the entire presenting mass is a pedunculated process of preperitoneal fat. These fatty protrusions are attached to the

parietal peritoneum and if the aperture through which the fat protrudes is not repaired at this stage, more and more fat gradually extrudes and eventually pulls a diverticulum of peritoneum with it. Into this peritoneal pouch, then, a viscus may herniate. This is the mechanism of the development of epigastric hernias and is referred to as the lipoma theory of Cloquet.

If one adheres to the classic definition, these fatty protrusions do not represent hernias, nevertheless they produce a palpable mass which is usually tender and produces symptoms which bring the patient to the doctor. These fatty protrusions are usually irreducible and in the inguinal canal may not be differentiated from a bowel-containing process of peritoneum. Another aberration of this definition is the reducible hernia and the majority of hernias are reducible in their early stages of development. A patient who has had a loop of bowel protruding through an aperture in the abdominal wall, and then has this loop of bowel return to the abdominal cavity, certainly has a hernia from a practical standpoint, although the viscus no longer protrudes.

Many patients live their entire lives with a congenital processus vaginalis in the in-

guinal canal without bowel or omentum ever entering this preformed sac. Therefore, from their standpoint or that of an examining physician, they have never had a hernia. A peritoneal sac is generally considered to be a component of a hernia, but this is not necessarily so. Traumatic hernias of the diaphragm rarely have a peritoneal sac unless they begin as small ruptures of the musculoaponeurotic structure which leave the peritoneum and pleura intact. A wound dehiscence is certainly a protrusion of abdominal viscera without a peritoneal covering.

Thus it is apparent that the definition of a hernia is not such a simple matter. Furthermore, the mass or size of the hernia, whether it is contained in a peritoneal sac, and whether it is reducible or irreducible are not the important considerations. The important point is the defect in musculoaponeurotic and fascial continuity or, more simply, the hole through the parietal abdominal wall (respiratory or pelvic diaphragms). It is the size of this defect which is the crux of the repair problem. The fixation and rigidity of the hernial ring are frequently important factors in reducibility and the incidence of strangulation. The size of the hernial sac is of no particular consequence from the standpoint of repair except in the very large variety where the replacement of viscera long outside the abdominal cavity may present a spatial problem.

Therefore, perhaps a better definition of a hernia would be one directed at the defect, to wit: *An abdominal hernia is a defect in the normal musculoaponeurotic and fascial continuity of the abdominal wall (respiratory or pelvic diaphragms), either congenital or acquired, which permits the egress of any structures other than those which normally pass through the parietes.* Thus, intermittency of protrusion, peritoneal sac or not, viscus or fat, would not confuse the definition. If one could diagnose a peritoneal sac with relative certainty, as in cryptorchidism or intermittent hydrocele, a diagnosis of a hernia could then be made even though there had never been an intra-abdominal viscus in the hernial sac. Hernias of the brain, lung, muscle and joint synovia occur, but to include them in a consideration of abdominal hernias would require a much broader definition and would needlessly complicate the picture.

Classification. There are many descriptive adjectives used in any discussion of hernias. *Topographic* refers to the regional location of the hernia, e.g., inguinal, femoral, umbilical or epigastric.

Congenital or acquired hernias would seem to be clear-cut terms and, as the words imply, divide all hernias into those present at birth and those which come on in later life, but some hernias are not categorized that easily. While there is not much doubt about absent segments of the respiratory diaphragm and omphalocele being congenital hernias, certain hernias considered to be acquired have a congenital predisposition to the development of the hernia. For example, the indirect inguinal hernia that develops in adulthood has had the peritoneal sac since the descent of the processus vaginalis which preceded the descent of the testis. *Reducible or irreducible (incarcerated)* refers to whether or not the contents of the hernia can be pushed back into the abdomen. Incisional hernias frequently have both reducible and irreducible components. *Strangulated* hernia is an irreducible hernia with compression obstruction of the blood supply to the incarcerated loop of bowel. If this is not relieved surgically in a few hours, the strangulated hernia becomes *gangrenous*. An *incisional* hernia occurs through a surgical incision or scar, is man made and in this instance there is no question that the hernia is acquired. *Recurrent* hernia is one which recurs following an operation for a similar type of hernia. In the inguinal region, this becomes a moot point. After repair of an indirect inguinal hernia, if the patient develops a direct inguinal hernia or a femoral hernia, does this represent a recurrence, is it a separate, subsequently acquired hernia, was this second hernia present all the time and simply missed at the original operation, or did the surgeon damage the posterior inguinal wall at the original operation and thereby lay the groundwork for the development of the second hernia? The term *double* usually refers to bilateral inguinal or femoral hernias but is also used to describe a direct-indirect inguinal hernia on a single side. A direct-indirect inguinal hernia, with the double sac straddling the inferior epigastric blood vessels, is also known as a *pantaloon* hernia. Very occasionally one encounters a direct inguinal, an indirect inguinal and a femoral hernia on the same side. In this event it is known as a *triple* hernia. An *external* hernia is one that protrudes to the outside where it is visible and palpable. An *internal* hernia is one that remains within the confines of the body cavities. Diaphragmatic hernia is an example of an internal hernia. Occasionally, one sees a hernia through the foramen

of Winslow, into a deep peritoneal recess or pouch, or through a traumatic rent in the omentum or mesentery. However, hernias of this type are extremely rare and most so-called internal hernias within the abdominal cavity represent congenital malrotations of the intestinal tract. A *sliding* hernia is one in which a viscus forms part of the wall of the hernial sac. *Hernia adiposa* is one in which the mass consists entirely of preperitoneal fat and is commonly seen in the epigastrium. *Littre's hernia* (Lavater's or Richter's hernia) is a type of incarcerated or strangulated hernia in which only a portion of the circumference of the bowel is caught in the hernial ring. *Spiegel's hernia* occurs in the linea semilunaris at or below the linea semicircularis but above the point at which the inferior epigastric vessels cross the lateral border of the rectus abdominis muscle. If it occurs below the inferior epigastric vessels, then it must be termed a direct inguinal hernia. An *interstitial* hernia develops and enlarges between the musculo-aponeurotic laminae of the abdominal wall rather than in the subcutaneous fascia. *Complete* or *incomplete* usually refers to the indirect inguinal hernia and the extent of the congenital peritoneal sac. A complete indirect inguinal hernia is one in which no portion of the processus vaginalis has become obliterated so that the hernial contents extend into the tunica vaginalis of the testis (inset, Fig. 4 a). An incomplete indirect inguinal hernia may also extend into the scrotum, but the sac does not communicate with the tunica vaginalis of the testis because the lower portion of the processus vaginalis has become obliterated (inset, Fig. 2 a).

Etiology. The etiologic basis of a given hernia may be an obvious single defect, but more commonly the cause is a combination of predisposing factors. The congenital hernias of infancy may be ascribed to a single etiologic factor which is either a congenital defect, such as omphalocele congenitalis, or failure of segmental development, as in the absence of a portion of the abdominal wall or respiratory diaphragm. An additional type of truly congenital hernia is the indirect inguinal hernia which appears at birth or soon thereafter. This distinction in timing in the development of the most common of all hernias is made to eliminate the contributing factors, such as increased intra-abdominal pressure and muscle relaxation, which are etiologic in the development of the indirect inguinal hernia in

adulthood. Rarely, trauma to the abdominal wall is the direct cause of a hernia, but, aside from penetrating wounds, the effect of trauma is usually transmitted to the weakest point and may be at some distance from the point of the injury. A blunt force to the central portion of the abdominal wall may result in the occurrence of a diaphragmatic hernia, a direct inguinal hernia, an indirect inguinal hernia or a femoral hernia. In the latter two examples, however, congenital predisposition is also an important factor. For example, unless there is a preformed sac in the inguinal canal no amount of trauma will produce an indirect inguinal hernia. In the case of the femoral hernia, the point is debatable. In an incisional hernia, the cause is the previous operative incision although here again there are contributing factors such as hemorrhage, infection or increased intra-abdominal pressure in the immediate postoperative period.

Heredity, or the *familial* tendency to hernia, is an obvious fact when one reviews the case records of many hernias. Persistence of the processus vaginalis in the inguinal canal, with an abdominal inguinal ring large enough to permit the development of a hernia, is certainly a familial tendency. Likewise, the generalized weakness of connective tissue as seen in the asthenic individual with visceroptosis and varicose veins is hereditary and these individuals more commonly develop hernias than does the general population. Any statistical evaluation of the hereditary influence on the incidence of hernia (such as the figure 25 per cent) must, however, be plotted against the overall incidence of hernia in the general population (variously estimated at between 1:8 and 1:15). Racial differences are probably more related to habits of nutrition and physical development than to any racial characteristic.

Age as an etiologic factor has two considerations. First, the incidence of all types of hernias as related to age and, second, age as related to a specific type of hernia. For example, direct inguinal hernia is a disease of advancing years and is rarely seen in children. Indirect inguinal hernia is more common in persons in the younger years, having its greatest incidence in the first year of life and a gradually decreasing incidence after that until the mid-teens when there is a sharp rise again which lasts until the mid-twenties. This is undoubtedly due to the period in which the most vigorous physical exercise occurs. The incidence of indirect

inguinal hernia then stays rather stationary until the sixth decade when it again falls off.

Sex as a determining factor in the development of a hernia is concerned with the type of hernia and developmental factors peculiar to the sex. The indirect inguinal hernia is nine times more common in the male than in the female because of the embryologic descent of the testes. Femoral hernia is three times more common in the female than in the male, presumably because of the difference in the inclination of the pelvis and the common occurrence of increased intra-abdominal pressure due to pregnancy. Adult umbilical hernia is two to three times more common in the female because of the element of pregnancy. Direct inguinal hernia is a rarity in the female for reasons unknown, but, from cadaver examination and examination of the posterior inguinal wall during the repair of indirect inguinal and femoral hernias in the female, it would appear that the posterior inguinal wall is a much heavier aponeurotic layer in the female than in the male.

Obesity in the young adult probably has very little effect upon the incidence of the various hernias, but in the older age groups it very definitely increases the incidence of epigastric and umbilical hernias, especially in the pregnant female. Obesity operates in two ways to increase the incidence of these two hernias: first, by increasing intra-abdominal pressure and, second, by forcing fat into tiny apertures, such as the perforating blood vessel foramina in the linea alba above the umbilicus (epigastric hernia), or through a persistent defect at the umbilicus (umbilical hernia). In the aged obese patient, one can observe fatty infiltration of

a congenital sac. Obesity has already been mentioned as a cause of increased intra-abdominal pressure. Other obvious causes are intestinal obstruction, urethral obstruction, cough, straining, trauma, heavy lifting and pregnancy. Gradually increasing and steady pressure is not so likely to produce a hernia as are repeated and sudden surges of increased pressure as in coughing. Many a patient can time the onset of his hernia to a sudden cough or to an extreme muscular effort, especially when associated with the element of surprise. The shutter action of the abdominal inguinal ring and of the inguinal canal is a fact which largely explains why a physically active man does not develop an indirect inguinal hernia during his active years but suddenly develops the hernia in old age. The congenital sac was always there, but the abdominal inguinal ring was effectively closed by muscular effort until he reached the age of poor muscle tone and developed a chronic cough or suddenly engaged in a severe muscular effort. Occasionally, one sees the first evidence of a small umbilical defect with the development of ascites, in which event the fluid-containing umbilical bulge becomes a barometer of the degree of ascites. Intra-abdominal neoplasms rarely cause a hernia because they develop so slowly that there is no significant increase in intra-abdominal pressure. This is due to the gradual stretching of the abdominal musculature.

Incidence. The relative frequency of the various common hernias has been tabulated many times but, rather than borrow from existing tables, it was decided to make a survey of the incidence in recent years. The total number of hernioplasties (3395) listed in Table 1 is too small to draw any definite conclusions. However, it is interesting to note that the percentages have remained roughly the same in the past fifty years, with the exception that incisional hernias are increasing in numbers. This is a natural sequence to the increasing number of operations performed each year.

The first group of 1065 consecutive hernioplasties was performed on our service at Sacred Heart Hospital in Yankton, South Dakota, between the years 1947 and 1954. This group represents the percentages in a general hospital in a rural area.

The second group of 1330 consecutive hernioplasties was performed in Passavant Memorial Hospital, Chicago, Illinois, in recent years. This group represents the percentages in a private city hospital.

in the obese patient.

Musculoaponeurotic deficiencies of the abdominal wall are an anatomic fact with considerable variation in the strength of the flat muscles of the abdominal wall. This undoubtedly is a primary factor in the development of the direct inguinal hernia. A congenitally narrow insertion of the transversus abdominis aponeurosis into Cooper's ligament may be the principal etiologic factor in the development of a femoral hernia.

Increased intra-abdominal pressure is the major etiologic factor in the development of all acquired hernias and is the precipitating cause in the development of the indirect inguinal hernia, in spite of the existence of

Table 1. The Relative Incidence of the Common Hernias in Consecutive Hernioplasties

SOURCE AND NUMBER OF CASES	INDIRECT INGUINAL	DIRECT INGUINAL	FEMORAL	UMBILICAL	EPIGASTRIC	INCISIONAL	DIAPHRAGMATIC
Sacred Heart Hospital Yankton, S D	658	89	61	112	18	123	4
1065 Hernias	61 8%	8 3%	5 7%	10 5%	1 7%	11 5%	0 5%
Passavant Mem Hospital Chicago, Illinois	816	370	23	33	8	76	4

Johns Hopkins Hospital Baltimore, Maryland	573	53	29	175	27	111	32
1000 Hernias	57 3%	5 3%	2 9%	17 5%	2 7%	11 1%	3 2%
Total Hernioplasties	2047	512	113	320	53	310	40
3395	60 3%	15 1%	3 3%	9 4%	1 6%	9 1%	1 2%

The third group of 1000 consecutive hernioplasties was performed in Johns Hopkins Hospital, Baltimore, Maryland, between the years 1949 and 1951. This group represents the percentages from a city hospital with a large charity service.

Symptoms and Diagnosis. The subjective symptoms caused by a hernia are extremely variable and depend more upon the pressure exerted on the contents than upon the size of the hernia. A very large hernia containing several feet of intestine and a large wad of omentum may cause the patient only the vaguest of symptoms, whereas a small hernia tightly constricting a knuckle of bowel or omentum can cause severe local pain, referred pain and nausea. When a hernia becomes strangulated, then the symptoms are severe, progressive and, unless corrected promptly, lead to serious consequences and even death.

An indirect inguinal hernia containing incarcerated omentum may cause only slight discomfort locally but by traction on the omentum can cause a more distressing epigastric pain which may be mistaken for that due to a duodenal ulcer or gallbladder disease. The small epigastric or umbilical hernia can have all of the symptoms referred to the epigastrium by traction on the omentum.

A small and unrecognized femoral hernia may contain an incarcerated knuckle of urinary bladder and be attended with all the symptoms referable to the urinary system, i.e., frequency, urgency, terminal dysuria and even hematuria. An esophageal hiatus hernia may cause symptoms related to the heart (palpitation and substernal pressure) by pressure from the dilated stomach as it lies in the posterior mediastinum. A traumatic diaphragmatic hernia may have the

chief symptom of shortness of breath due to compression of the lung; pain in the base of the neck due to diaphragmatic irritation, or, if the parietal pleura is irritated, a typical pleuritic pain aggravated by deep breathing.

Whenever there is compression of the bowel lumen, there are the added and usually progressive symptoms of bowel obstruction. Even partial obstruction of the lumen, as in a Littre's hernia, can cause symptoms of bowel obstruction. When the blood supply to a viscus is compressed, one then sees the added signs and symptoms of a strangulating obstruction.

If the hernia is visible or palpable and the mass is painful, there is little doubt on the part of either the patient or the physician as to the diagnosis. Small epigastric hernias, especially in the obese, are difficult to detect. Hernias of the respiratory diaphragm are, of course, diagnosed with certainty only by an x-ray examination usually augmented by a contrast medium. Internal hernias are usually diagnosed only during an operation for intestinal obstruction.

Most hernias have a somatic component of local pain plus a referred element of visceral pain. It is in those cases, in which the patient's chief complaint is of visceral origin, that the diagnosis may not be entirely clear. Pain at the hernial site is directly related to the degree of irritation of the parietal peritoneum and adjacent somatically innervated structures. Pressure and inflammation are the precipitating factors. The pressure upon a contained viscus or its subsequent vascular injury is referred to the ganglia of the afferent visceral pain fibers, the superior mesenteric or celiac plexus, and is therefore felt by the patient as pain in the epigastrium. Some patients who have had a troublesome hernia for a long time learn

to localize visceral pain and, hence, have no referred symptoms.

Certainly the most common complaint of a patient with a hernia is a painful lump and it is the pain which usually brings the patient to the doctor. However, concern over the presence of a tumor, even when painless, will usually cause the patient to seek medical advice. The pain is intermittent when the hernia is reducible. It is absent when the hernia is reduced and usually mild when the hernia is "out," if it is of long standing. Especially in hernias with small rings and in hernias that have just made their appearance, the pain is quite sharp when the hernia comes down and again at the moment when it reduces.

The objective characteristics of a hernia are the presence of an abnormal swelling which may be so soft as to feel fluctuant, firm or hard, depending upon the contents of the sac and the pressure exerted. Omentum has a rather characteristic doughy feel, but so does a loop of sigmoid colon containing feces. A loop of gas-filled intestine may be very soft and compressible or very tense, depending upon the degree of incarceration. If a loop of intestine is strangulated, it is very tense and exquisitely tender. Except when incarcerated, the mass of the hernia can be made to disappear with gentle pressure, especially with the patient in the supine position. The patient is frequently more adept at reducing the hernia than is the examining physician because of long practice with his particular hernia and the fact that his muscles are more relaxed when he is not afraid that the physician will hurt him.

Another classic characteristic of a hernia is the reappearance of the tumor with straining or coughing after it has been previously reduced. Associated with the reappearance of the hernia are the sensations imparted to the physician's examining finger. This sensation has been variously described but can most simply be expressed as a push or impulse. An incarcerated hernia or a strangulated hernia is fixed, will not reduce and, of course, has no impulse on palpation. Transillumination with a strong light in a darkened room is a useful aid in differentiating a hydrocele of the cord from an incarcerated indirect inguinal hernia. The hydrocele will transilluminate, whereas the hernia containing bowel or omentum will not because of its greater density.

Percussion of a hernial mass will serve to differentiate a gas-containing viscus from a

solid wad of omentum. Auscultation over the hernial mass will occasionally serve to confirm the impression of an incarcerated loop of intestine. Auscultation over the abdomen is more important in determining the degree or status of intestinal obstruction when an incarcerated hernia is present and there are other signs of intestinal obstruction. X-ray examination of the intestinal tract with a contrast medium is rarely necessary for the diagnosis of a hernia of the abdominal wall. Occasionally, however, the barium enema examination of the colon will furnish the only evidence of an incarcerated knuckle of sigmoid colon (Littre's hernia) in an indirect inguinal hernial sac.

Treatment. The treatment of a hernia is surgical correction of the defect in normal musculoaponeurotic structure. The operation should have as its principal objective the restoration of the hernial area to as near the normal status as is possible. Except in patients with large incisional hernias and in those with congenital absence of portions of the abdominal wall or respiratory diaphragm, normal anatomy can usually be restored.

Methods other than the surgical correction of the anatomic defect are occasionally indicated but are of secondary importance. The injection treatment of hernias was a popular method in Europe for years and gained its greatest popularity in this country in the 1930's, but experience has shown that it rarely cures a hernia and it has been abandoned. In the first few years of its use, it apparently cured small indirect inguinal hernias but, eventually, most of these hernias reappeared. The scarring incident to the injected sclerosing solution makes the surgical repair extremely difficult.

Some patients refuse operation even though the need is urgent; in other instances, there is a strong contraindication to subjecting the patient to the risk of an operation because of associated serious systemic disease. Such patients whose hernia is amenable to compression reduction should be fitted with an appropriate truss. However, the decision as to the type of truss and the suitability of the hernia to truss treatment requires experience. An improperly fitting truss, or a truss applied to the wrong type of hernia, not only can be painful but can increase the likelihood of damage to the contents of the hernial sac. The small indirect inguinal hernia is the best type of hernia for the application of a truss. However, it is also one of the easiest to repair surgically

and, if local anesthetic is used, there are very few contraindications to the operative correction of this hernia.

The yarn truss, which has been used for years in the management of the indirect inguinal hernia in the infant, still has a place in premature infants or the newborn in whom an anesthetic would carry an excessive risk. However, in the past few years most surgeons now correct these hernias in the infant irrespective of age. Present-day anesthesia and knowledge of nutrition, electrolyte and fluid requirements for infants make the operation no more hazardous than for older children. In fact, when properly managed, even the newborn withstands the operation well. Operation not only corrects the defect promptly, but these children progress better in their development than those with recurrent bouts of trouble with a hernia. It also removes the hazard of strangulation which a yarn truss does not; in fact, one occasionally sees a vomiting infant with an incarcerated hernia and yet the mother thought that she had the yarn truss properly applied. At present we are still willing to procrastinate in the case of a small umbilical hernia up to one year, in the hope that the ring will close with compression treatment. We now advise operation upon the infant with an indirect inguinal hernia as soon as the diagnosis is made.

In planning a hernia operation upon a given patient the surgeon should carefully consider the patient as a whole. This is especially true in persons of the older age groups. The cardiovascular and renal systems should be carefully evaluated, on our service, a preoperative x-ray examination of the chest is mandatory. Even though the x-ray film of the chest shows no abnormality, this evidence may be of the most vital importance in evaluating postoperative pulmonary complications. In the older group of patients who suddenly develop a hernia, causes of increased intra-abdominal pressure should be carefully searched for in the preoperative work-up. The patient with an obstructing carcinoma of the colon or urethral obstruction due to benign prostatic hypertrophy or carcinoma should not be subjected to a hernia operation unless the hernia is strangulated. If at all possible, the obese patient should be reduced to near normal weight before undergoing an elective hernia operation. The operation is not only more difficult technically, but the incidence of recurrence and postoperative complications is much higher in the obese patient than in one of normal weight.

HERNIAS OF THE INGUINOFEMORAL REGION (GROIN HERNIAS)

This rather general heading is used so that inguinal and femoral hernias may be considered together. It has been customary in the past to discuss the femoral hernia as a separate entity, but the point should be emphasized that a femoral hernia is in reality a type of inguinal hernia. Although the etiologic factors of the indirect inguinal hernia, the direct inguinal hernia and the femoral hernia are different, the effect of these hernias upon the posterior inguinal wall is so interrelated that they must be considered together if one is to understand first, the altered anatomic structure and, second, the rational repair.

Although the sac of the femoral hernia lies in the fossa ovalis of the femoral region the defect which allows the hernia to develop is just as truly inguinal in location as is the defect which permits the development of a direct inguinal hernia, or the enlarged abdominal inguinal ring of an indirect inguinal hernia even though the sac of the latter may extend into the scrotum. Therefore, the femoral hernia will be presented as simply a variety of inguinal hernia.

INDIRECT INGUINAL HERNIA

Definition. An indirect inguinal hernia is one which passes through the abdominal inguinal ring and follows the course of the spermatic cord in the inguinal canal and then emerges through the subcutaneous inguinal ring. A very small sac may be confined to the inguinal canal, whereas the complete congenital peritoneal sac extends into the scrotum to communicate with the tunica vaginalis of the testis (Fig. 4 a and inset).

Etiology. The primary etiologic factor of the indirect inguinal hernia is the presence of a congenital diverticulum of peritoneum which passes through the abdominal inguinal ring and into the inguinal canal. This is due to failure of the processus vaginalis to obliterate after the descent of the testis in the male and after fixation of the ovary in the female. It may be a short sac or extend into the scrotum and communicate with the tunica vaginalis of the testis (insets Figs. 2 a and 6 a). A necessary contributing etiologic factor is increased intra-abdominal pressure sufficient to force a viscus into the preformed peritoneal sac.

Incidence. This is not only the most common type of groin hernia but the most common of all hernias (Fig. 1). The fact that it represents more

all hernias and over 80 per cent of the groin hernias very adequately expresses the importance of the proper understanding of the pathologic anatomy of this hernia and its operative repair. It is ten times more common in the male than in the female.

Anatomy. The normal anatomic structure of the inguinofemoral region is presented in Figure 1 a and b. The distortion of the normal anatomic relationship by the presence of an indirect inguinal hernia can best be presented by dividing the indirect inguinal

Figure 1 The normal anatomic structure of the inguinofemoral region. a, Anterior view. b, Posterior view. The numbers 1, 2 and 3 represent the sites of origin respectively of the indirect inguinal, the direct inguinal and the femoral hernia

hernias into three categories, depending upon the size of the dilated abdominal inguinal ring. The length of the sac or the quantity of the contents of the hernia is of no particular importance. The crux of the repair problem is the size of the abdominal inguinal ring and on this basis the pathologic anatomy of this type of hernia will be discussed under the headings of small, medium and large indirect inguinal hernia.

Small indirect inguinal hernia (Fig. 2). All indirect inguinal hernias are in this category at their outset. Irrespective of the length of the congenital peritoneal sac, there is only very slight dilatation of the abdominal inguinal ring. Aside from the presence of the congenital peritoneal sac, the only alteration of the normal anatomic state is the minimal stretching of the abdominal ring (Fig. 2 b and c). The posterior inguinal wall (transversus abdominis muscle, aponeurosis and fascia) is intact, the femoral ring is small and even the continuity of the transversalis fascia into the anterior femoral sheath medial to the slightly dilated abdominal inguinal ring is normal. Therefore it should be apparent that the repair of this most common of all hernias should be a very simple problem.

Medium indirect inguinal hernia (Fig. 3). The selection of this category is arbitrary to illustrate a point. As pointed out above, the small indirect inguinal hernia has only the slightest alteration from the normal anatomic relationships. The large indirect inguinal hernia may cause complete destruction of the posterior inguinal wall and its repair involves the same problems as does the direct inguinal hernia. In between these two extremes there is great variation in the dilatation of the abdominal inguinal ring. As the ring is enlarged slowly by the presence of the hernia, it expands medially for the most part. Eventually a point is reached which determines whether the hernia can be repaired by simple closure of the dilated abdominal inguinal ring or whether the posterior wall must be reconstructed. From our experience, it has been determined that this point is a line drawn cephalad from the femoral ring. If the dilated abdominal inguinal ring extends medially beyond this line, the hernia must be repaired as for a large indirect inguinal hernia and, conversely, if it remains lateral to this line the hernia may be simply repaired by closing the dilated abdominal inguinal ring.

The term medium indirect inguinal hernia, then, refers to a hernia with an ab-

dominal inguinal ring which has dilated up to this line (Fig. 3 b and c). In this hernia, in addition to the congenital peritoneal sac, the pathologic anatomy consists of complete destruction of the continuity of the transversalis fascia into the anterior femoral sheath by the enlarged abdominal inguinal ring. However, the posterior inguinal wall and its insertion into Cooper's ligament are undisturbed.

Two other variations of the normal anatomic relationship are common in both this size of indirect inguinal hernia and in the large variety: protrusion of pedunculated processes of preperitoneal fat among the cord structures (Fig. 3 b), and the incorporation of a hollow viscus in the wall of the hernial sac, known as a sliding hernia.

Large indirect inguinal hernia (Fig. 4). It should be understood that this hernia began as the small variety and in sequence was a medium indirect inguinal hernia before becoming a large indirect inguinal hernia. It therefore takes considerable time for the development of this type of indirect inguinal hernia. Any indirect inguinal hernia, with the abdominal inguinal ring dilated medially beyond the line drawn cephalad from the femoral ring, is termed a large indirect inguinal hernia. It should be realized that just as there is considerable variation between the size of a small and a medium indirect inguinal hernia, there is also a great variety of sizes of dilated abdominal rings between the medium indirect and the largest possible indirect inguinal hernia which are all designated large indirect inguinal hernias. In the very large variety, the medial margin of the dilated abdominal inguinal ring extends to the lateral margin of the rectus abdominis muscle (Fig. 4 b and c). Anatomically, this means that a posterior inguinal wall is non-existent.

In the slow transition of a small indirect inguinal hernia into the very large variety, there are several features which are of importance. In the indirect inguinal hernia, the peritoneal sac is always on the anteromedial aspect of the spermatic cord as it lies in the inguinal canal, except in the recurrent indirect inguinal hernia, where it may bear any relationship to the cord structures. This constant position of the peritoneal sac goes back to the embryologic descent of the testis. Prior to the descent of the testis, the processus vaginalis of the peritoneum descends into the scrotum. The testis, which is a retroperitoneal structure, slides into the scrotum behind and slightly ahead to the

The line of separation of the cremaster muscle from the internal oblique is denoted by * c, Posterior view of the moderately dilated abdominal ring

peritoneal sac, therefore, when the processus vaginalis fails to obliterate, the indirect inguinal hernial sac is already in position waiting to receive a viscus and become an indirect inguinal hernia.

As the abdominal inguinal ring enlarges in the transition from a small to a medium to a large indirect inguinal hernia, this enlargement takes place predominantly in a medial direction. The origin of the lower fibers of the internal oblique and transversus abdominis muscles from the fascia lata lateral to the abdominal inguinal ring prevents any significant enlargement in this direction. Inferiorly or caudally, the inguinal ligament over the iliac vessels and, more medially, the superior ramus of the pubic bone prevent enlargement in this direction. Superiorly, there is some extension, but the abdominal musculature prevents much enlargement in this direction. Therefore, with rather rigid restrictions superiorly, laterally and inferiorly, it can be seen that the abdominal inguinal ring enlarges medially at the expense of the posterior inguinal wall (transversus abdominis aponeurosis). As the posterior inguinal wall is stretched and attenuated, it is pushed outward and becomes part of the internal spermatic fascial investment of the hernial sac. The lateral border of the rectus abdominis muscle and tendon of origin stop the medial enlargement of the abdominal inguinal ring. When a ring of this size is reached, there is never any significant increase in size no matter how long the hernia persists or how many of the abdominal viscera descend into the hernial sac. In the enormous scrotal hernias, there is some stretching of the musculature along the superior margin of the ring, but, for all practical purposes, the rectus muscle is the final delimiting factor in the size of the ring.

Diagnosis. The diagnosis of this type of hernia is dependent upon the demonstration of the course of the hernial sac through the inguinal canal. The hernia begins at the abdominal inguinal ring, traverses the inguinal canal and emerges into the upper scrotum or greater labia at the subcutaneous inguinal ring. The descent of the sac into the scrotum is variable in degree and is dependent upon the original size of the congenital sac and upon the duration of the hernia. A scrotal hernia is invariably an indirect inguinal hernia, although rarely a direct inguinal hernia may extend well down into the scrotum, statements to the contrary notwithstanding. Usually the diagnosis of this type of hernia is made with ease by following a few simple

diagnostic maneuvers. In a slender individual, observation will be sufficient to make the diagnosis because the bulge of the hernia can be seen to begin at the abdominal inguinal ring, follow the course of the inguinal canal and emerge at the subcutaneous inguinal ring. If the external oblique aponeurosis is a strong layer with heavy intercrural fibers, the only bulge visible may be at the subcutaneous inguinal ring. In the obese patient or when the hernia is incipient, one must use palpation to make the diagnosis.

The classic maneuver of invaginating the scrotal skin with the index finger and then advancing the end of the finger through the subcutaneous inguinal ring helps to make the diagnosis in several ways. With the hernia reduced and the end of the examining finger through the subcutaneous inguinal ring, a sudden cough by the patient will demonstrate the oblique course of the hernia down the length of the inguinal canal. Sometimes it is difficult to tell whether the hernia is direct or indirect, especially when the subcutaneous inguinal ring is too small to admit the end of the examining finger. When this is the case, digital pressure over the abdominal inguinal ring will prevent the descent of the hernia if it is of the indirect variety, whereas the bulge will still be felt if it is a direct inguinal hernia.

The patient should be examined in both the standing and the recumbent position for adequate evaluation of the hernia. Even in a patient having an obvious indirect inguinal hernia, the strength of the posterior inguinal wall should be evaluated before the operation because the patient can voluntarily contract his muscles. This is done with the patient in the recumbent position with the end of the examining finger through the subcutaneous inguinal ring and the indirect hernia reduced. The posterior inguinal wall is then indented by pressure posteriorly with the end of the finger and the patient asked to strain forcibly as when having a bowel movement. If the posterior inguinal wall is strong and intact, a firm, hard layer will be felt. If the hernia is direct or if there is a combined direct and indirect inguinal hernia, contraction of the abdominal muscles as in straining gives no sensation of a firm layer against the end of the examining finger. In fact, with the patient straining, the fingertip may be moved in and out with ease and the superior edge of the superior pubic ramus plainly felt. This is the location of Cooper's ligament. This last combined maneuver is an important of the pre-

operative examination, especially for the beginner, because at the operating table with the patient asleep it is sometimes difficult to evaluate the strength of the posterior inguinal wall.

As has been mentioned, a direct inguinal hernia may be confused with an indirect inguinal hernia or may coexist as a double or "pantaloon" hernia. A femoral hernia may curve cephalad over the inguinal ligament and superficially resemble an indirect inguinal hernia, but careful examination should serve to differentiate the two. Although the inguino-femoral group of lymph nodes lies below the inguinal ligament, these nodes do rise above or cephalad to the ligament when enlarged and in certain individuals may very closely resemble an incarcerated indirect inguinal hernia.

A large varicocele may resemble an indirect inguinal hernia, but it lacks the feel of a hernial sac, does not give the typical impulse and is irreducible. It may give a slight impulse with coughing due to increased venous pressure and can be decreased in size by compression, but it has a characteristic sensation to palpation often described as a "bag of worms."

An incompletely descended testis lying in the inguinal canal may feel like the present end of a hernial sac and is frequently seen in children. It is our belief that unless the testis has descended by the time the child reaches the age of six or seven years, it should be placed in the scrotum surgically and that the use of Antutrin-S is not warranted. In those few patients in whom it seems to effect a further descent of the testis, it is likely that the effect is pure coincidence. Behind an incompletely descended testis one invariably finds a persistent processus vaginalis which, of course, is the precursor of an indirect inguinal hernia.

Tumors of the testis and hydrocele of the tunica vaginalis of the testis should not cause confusion because the cord above the swelling is normal in size. Hydrocele of the cord, however, particularly if it extends up through the subcutaneous inguinal ring, may simulate an incarcerated indirect inguinal hernia. Neither an incarcerated hernia nor a hydrocele gives an impulse, but the hydrocele will transilluminate and the incarcerated hernia will not. Occasionally, one sees a hydrocele which disappears overnight or becomes soft and much smaller. This is direct evidence that a small communication exists through a persistent processus vaginalis and that a hernial sac exists. This type

of hydrocele should be treated surgically if an indirect inguinal hernia and the sac completely removed. In the presence of hydrocele of the cord, one should always look for a coexistent indirect inguinal hernia because, whether there has ever been an act of hernia or not, a persistent processus vaginalis is commonly associated.

A hernia adiposa in the inguinal canal closely resembles an incarcerated indirect inguinal hernia that the two cannot be differentiated. As a matter of fact, a hernia adiposa does constitute a true hernia even in the absence of a peritoneal sac. In a event, the protrusion of preperitoneal fat through the abdominal inguinal ring will have dilated the ring and, therefore, it needs surgical correction.

Treatment. In the small indirect inguinal hernia there is practically no alteration of the normal anatomic structure. The persistent processus vaginalis which is the hernial sac must, of course, be removed and the adequate removal of this sac with ligation has long been a standard procedure. After dissecting the peritoneal sac free from the cord structures well up through the abdominal inguinal ring, all that needs to be done to return the inguinal region to normal is to tighten the ring to normal size (Fig. 6 a and b). Any additional approximation or plication of the layers is not only unnecessary but may damage an otherwise normal posterior inguinal wall. After the abdominal inguinal ring is returned to normal size, the spermatic cord is dropped back into its normal position and the external oblique aponeurosis is sutured together making a snug subcutaneous inguinal ring (Fig. 6 c).

After the peritoneal (hernial) sac is removed, the medial margin of the slightly dilated abdominal inguinal ring is delineated by sharp dissection. This is very simply accomplished by cutting the internal spermatic fascia at its point of origin from the transversalis fascia. This clearly demonstrates the margin of the medial half of the slightly dilated abdominal inguinal ring without disturbing the fascial and muscular attachments of the lateral half of the ring which need not be disturbed. It also demonstrates the fascial continuity of the transversalis fascia into the anterior layer of the femoral sheath. It is upon this anatomic fact that the rationale for the repair of this type of hernia is based. The dilated abdominal inguinal ring is reduced to normal size by suturing the transversalis fascia to the anterior layer of the femoral sheath (Fig. 6 b).

Fig. 6

Fig. 7

Figure 6. Hernioplasty for small indirect inguinal hernia (viewed from right). a, b and c, Successive steps in the operation.

Figure 7. Hernioplasty for medium indirect inguinal hernia (viewed from right) in the female. a, b and c, Successive steps in the operation showing obliteration of the abdominal inguinal ring.

Frequently the external spermatic vessels do not pass through the abdominal inguinal ring but through a separate foramen more medially placed. If they cannot be pulled lateralward into the abdominal inguinal ring, they are cut between ligatures to avoid leaving an aperture through which fat might protrude.

The repair of a *medium indirect inguinal hernia* is essentially the same as that of the small indirect inguinal hernia except, of course, that the abdominal inguinal ring is larger and it takes more sutures to return the ring to normal size (Fig. 7 b). The principle of repair is identical in that the transversalis fascia is sutured to the anterior layer of the femoral sheath. When an indirect inguinal hernia is repaired in the female, the round ligament is removed with the hernial sac, which permits complete closure of the abdominal inguinal ring. This is the ideal hernia repair for the beginner to undertake, because the continuity of layers is clear and one is not faced with the complicating feature of structures passing through the inguinal canal.

In addition to the presence of the congenital hernial sac, a *large indirect inguinal hernia*, because of the greatly enlarged abdominal inguinal ring, has destroyed the posterior wall of the inguinal canal. Therefore, in accomplishing the repair of this type of hernia, one must not only remove the hernial sac and make a snug abdominal inguinal ring as in the two foregoing types of hernias, but one must also reconstruct a new posterior inguinal wall (Fig. 8).

Through the years, innumerable devices have been used to obtain muscular, aponeurotic and fascial material to replace the posterior inguinal wall. Some of them have merit while others are based on false anatomic premises. Furthermore, any hernioplasty which fastens the new posterior inguinal wall to the inguinal ligament is anatomically unsound. One should carefully study the normal anatomy of the inguinal region as presented in Figure 1, for it is upon a thorough understanding of the normal anatomy that the rational repair of groin hernias is based. In other words, it should be the object of every hernia operation to return the region to the normal anatomic state.

When the posterior inguinal wall is destroyed in part or in toto by a large indirect inguinal hernia, aponeuroticofascial tissue must be borrowed somewhere to close the defect. The simplest device is to use the

aponeurosis and fused fasciae of the transversus abdominis immediately above and medial to the defect (Fig. 8). This aponeuroticofascial plate also contains the lowest aponeurotic fibers of the internal oblique muscle and, of course, where it lies over the rectus abdominis muscle it is known as the rectus sheath. This layer is the ideal material because it is primarily aponeurotic. The fasciae, of which the innermost layer is the transversalis fascia, serve to bind the aponeurotic fibers together into a firm and intact layer. Fascia or muscle does not meet the requirements for a satisfactory layer to close a hernial defect.

Another sound surgical principle is that layers should be approximated without tension. If one sutures the strong edge of the transversus abdominis aponeurosis to Cooper's ligament, there is considerable tension on the suture line. The same difficulty is encountered in the classic herniorrhaphies which use the inguinal ligament as the anchoring structure. To obviate tension, the "relaxing incision" (Fig. 8) should be used in every instance in which the posterior inguinal wall is reconstructed. This was first described by Halsted in 1911 and subsequently championed by Rienhoff and Fells. A modification of the relaxing incision is the turning downward of a triangular flap of the rectus sheath as described by Bloodgood and more recently by Farris. The "slide" of the rectus sheath made possible by the relaxing incision seems more physiologic than the flap method because the normal direction of musculoaponeurotic pull is maintained.

Preserved fascia, cutis grafts, osteoperiosteal grafts and flaps of fascia lata have all been used as patches for the posterior inguinal wall. While these methods have been used successfully by their proponents, we have never found it necessary to resort to transplanted material. However, should it seem advisable to reinforce the posterior inguinal wall after its reconstruction by the method to be briefly described, it would seem preferable to use a wire mesh, as described by Koontz.

Before the new posterior inguinal wall can be transferred into position, all of the attenuated old posterior inguinal wall and hypertrophied cord fasciae must be excised (Fig. 8). The peritoneal hernial sac must be dissected out and the neck of the sac ligated as for any indirect inguinal hernia. For an accurate repair of this hernia, one must have an evenly cut margin of trans-

versus abdominis aponeurosis above, from abdominal inguinal ring to Cooper's ligament. Below, the glistening margin of Cooper's ligament must be seen medially and the edge of the anterior femoral sheath laterally. When these margins have been carefully dissected and the peritoneal sac excised, one is then ready to repair the hernia (Fig. 8 c).

After making the relaxing incision (Fig. 8 a and b), the strong cut edge of the transversus abdominis aponeurosis is sutured to Cooper's ligament from the pubic tubercle to within a few millimeters of the external iliac vein (Fig. 8 d). This maneuver not only reconstructs the posterior inguinal wall, but it re-establishes a normally broad insertion into Cooper's ligament and thus obviates the possibility of the development of a femoral hernia. It should be noted that the relaxing incision (Fig. 8 d) is now a considerable defect in the rectus sheath, protected behind by the rectus and pyramidalis muscles and their fasciae.

The next suture is the "transition" suture which approximates the edge of the transversus abdominis aponeurosis to the medial wall of the femoral sheath and pectineus muscle fascia. This suture is necessary to close the angle and permit the line of closure to come up from the level of Cooper's ligament to the more superficial level of the anterior femoral sheath. This distance is represented by the diameter of the external iliac vein.

The remaining defect is closed by suturing the transversus abdominis aponeurosis or in case the layer is muscular at this point, the transversalis fascia, to the anterior layer of the femoral sheath. This re-establishes the normal continuity of transversalis fascia into the anterior femoral sheath. This line of sutures is continued laterally until a snare

cord is dropped in against the new posterior inguinal wall and the external oblique aponeurosis closed over it (Fig. 8 e and f), thus re-establishing the obliquity of the inguinal canal. The subcutaneous inguinal ring is snugly closed.

DIRECT INGUINAL HERNIA

Definition. A direct inguinal hernia is one that passes through the posterior inguinal wall medial to the inferior epigastric vessels in the area bounded by Hesselbach's triangle.

Etiology. The etiologic basis of the direct inguinal hernia is both congenital and acquired. The acquired factor in the development of this hernia is easy to understand because it is operative in the development of all hernias and is due to increased intra-abdominal pressure from whatever causes. Sudden or abrupt increase in the intra-abdominal pressure is more effective in producing a hernia than is a gradual increase in pressure.

The congenital predisposition to the development of a direct inguinal hernia is undoubtedly the most important etiologic factor. The robust common laborer is not prone to develop a direct inguinal hernia, nor is the asthmatic with paroxysms of violent coughing certain to develop this type of hernia. On the other hand, the asthenic individual with visceroptosis is not only the ideal candidate for the development of a direct inguinal hernia, but he is also more likely to have hemorrhoids and varicose veins than is a person of other body type. This suggests a congenital weakness of connective tissue throughout the body.

Direct inguinal hernia is a rarity in the female. This has been attributed to the flat, gynecoid pelvis of the female and a more even distribution of intra-abdominal pressures than in the male. While these anatomic facts may help to explain the low incidence of direct inguinal hernia in the female, it is also true that the posterior inguinal wall is almost always a heavy aponeuroticofascial plate in the female. Just why this is so, when as a rule the male has the better muscular development, cannot be explained, but it has been observed in the dissection of many cadavers and almost a thousand operations.

Irrespective of sex, body build, occupation or associated diseases that increase intra-abdominal pressure, the most important predisposing cause for the development of a direct inguinal hernia is a weak posterior inguinal wall. The posterior inguinal wall is the transversus abdominis aponeurosis with its investing fasciae and the strength of this wall is directly proportional to the number of aponeurotic fibers. The transversalis fascia is the layer that develops a direct inguinal hernia.

There is also considerable variation in the internal oblique layer in the inguinal region which has been observed and recorded by a number of surgeons, but we now consider

this layer of secondary importance in the development of direct inguinal hernia.

Occasionally, direct external trauma may be the etiologic basis of a direct inguinal hernia and, certainly, injury to the posterior inguinal wall during the repair of an indirect inguinal hernia or a femoral hernia will cause a direct inguinal hernia. In this instance, it is usually a "diverticular" type of direct inguinal hernia (Fig. 5 d).

Incidence. This hernia represents about 20 per cent of the groin hernias and from 10 to 15 per cent of all parietal abdominal hernias. While it is readily seen that this is not as common as the indirect inguinal hernia, it is the direct inguinal hernia which has baffled surgeons in the past half century and it is the hernia that is most likely to recur. The conventional inguinal ligament herniorrhaphies have been notably unsuccessful in repairing the direct inguinal hernia, recorded recurrence rates varying from 8 to 50 per cent.

Anatomy. The normal anatomy of the inguofemoral region is presented in Figure 1, in which the number 2 represents the site of direct inguinal hernia. Whatever combination of factors operate to cause a direct inguinal hernia, the immediate cause is, of course, a dissolution of the integrity of the posterior inguinal wall.

The most common type of direct inguinal hernia is not an actual hole through the posterior inguinal wall, but a gradual attenuation of an intact but congenitally weak transversus abdominis aponeurosis. It is weak because of a deficient number of aponeurotic fibers. As the bulge of the hernia becomes larger and larger, the aponeurotic fibers are spread farther and farther apart. The fasciae, of which the innermost or transversalis fascia is the heaviest, stretch but maintain the continuity of this layer.

As the transversus abdominis layer gives way and bulges forward, the overlying internal oblique muscle is stretched and pushed superiorly. The spermatic cord, with its investing cremaster, usually remains below the bulge of the hernia. This is due to the disruption of the delicate fascial connection between the lower edge of the internal oblique and the cremaster. A strong musculoponeurotic internal oblique layer may slow down the development of a direct in-

However, this much is true—a deficient internal oblique layer in the inguinal region is frequently associated with a deficient transversus abdominis layer. The important point to understand is that the transversus abdominis aponeurosis with its investing fasciae is the key to the development of a direct inguinal hernia. If this layer is strong and intact, a direct inguinal hernia will not develop even though the internal oblique and external oblique layers are very weak or deficient. On the other hand, if the transversus abdominis layer begins to attenuate and bulge, the patient will develop a direct inguinal hernia in spite of a strong overlying internal oblique muscle.

The strength of the external oblique aponeurosis is of even less importance than the internal oblique muscle, for the developing hernia easily protrudes through this layer between the crura of the subcutaneous inguinal ring. This space between the aponeurotic crura of the external oblique aponeurosis is commonly referred to as a ring; actually it is a long triangle with the aponeurotic defect bridged by the innominate fascia. It is variable in strength, depending upon the number of intercrural fibers. When the hernia has passed through the external oblique layer, it enlarges in size in the subcutaneous fascia in the vicinity of the subcutaneous inguinal ring.

Hesselbach's triangle, bounded by the inguinal ligament, the inferior epigastric vessels and the lateral border of the rectus abdominis muscle, is a convenient descriptive area. Direct inguinal hernias must pass through this triangle. If a hernia occurs lateral to the inferior epigastric vessels, it is an indirect inguinal hernia. If a hernia occurs below the inguinal ligament, it is a femoral hernia. If a hernia occurs above the inferior epigastric vessels in the linea semilunaris, it is a Spiegel's hernia. Occasionally the sac of a direct inguinal hernia will straddle the obliterated hypogastric artery to form a pantaloon type of sac. However, this is a curiosity rather than of any particular significance and we place no emphasis upon whether the hernia has presented through the supravesical fossa or the medial inguinal fossa.

The pathologic anatomy of the common type of direct inguinal hernia has been described. Rarely, one sees a direct inguinal hernia with a small neck and these are described as a diverticular type of direct inguinal hernia (Fig. 5 d). This hernia proceeds through the layers of the abdominal wall in

may, the significance of the so-called inguinal triangle in the causation of a direct inguinal hernia is certainly questionable

versus abdominis aponeurosis above, from abdominal inguinal ring to Cooper's ligament. Below, the glistening margin of Cooper's ligament must be seen medially and the edge of the anterior femoral sheath laterally. When these margins have been carefully dissected and the peritoneal sac excised, one is then ready to repair the hernia (Fig 8 c).

After making the relaxing incision (Fig. 8 a and b), the strong cut edge of the transversus abdominis aponeurosis is sutured to Cooper's ligament from the pubic tubercle to within a few millimeters of the external iliac vein (Fig. 8 d). This maneuver not only reconstructs the posterior inguinal wall, but it re-establishes a normally broad insertion into Cooper's ligament and thus obviates the possibility of the development of a femoral hernia. It should be noted that the relaxing incision (Fig. 8 d) is now a considerable defect in the rectus sheath, protected behind by the rectus and pyramidalis muscles and their fasciae.

The next suture is the "transition" suture which approximates the edge of the transversus abdominis aponeurosis to the medial wall of the femoral sheath and pectineus muscle fascia. This suture is necessary to close the angle and permit the line of closure to come up from the level of Cooper's ligament to the more superficial level of the anterior femoral sheath. This distance is represented by the diameter of the external iliac vein.

The remaining defect is closed by suturing the transversus abdominis aponeurosis or in case the layer is muscular at this point, the transversalis fascia, to the anterior layer of the femoral sheath. This re-establishes the normal continuity of transversalis fascia into the anterior femoral sheath. This line of sutures is continued laterally until a snug abdominal inguinal ring is made just as it is done for the repair of the small- to medium-sized indirect inguinal hernia. The spermatic cord is dropped in against the new posterior inguinal wall and the external oblique aponeurosis closed over it (Fig 8 e and f), thus re-establishing the obliquity of the inguinal canal. The subcutaneous inguinal ring is snugly closed.

DIRECT INGUINAL HERNIA

Definition. A direct inguinal hernia is one that passes through the posterior inguinal wall medial to the inferior epigastric vessels in the area bounded by Hesselbach's triangle.

Etiology. The etiologic basis of the direct inguinal hernia is both congenital and acquired. The acquired factor in the development of this hernia is easy to understand because it is operative in the development of all hernias and is due to increased intra-abdominal pressure from whatever causes. Sudden or abrupt increase in the intra-abdominal pressure is more effective in producing a hernia than is a gradual increase in pressure.

The congenital predisposition to the development of a direct inguinal hernia is undoubtedly the most important etiologic factor. The robust common laborer is not prone to develop a direct inguinal hernia, nor is the asthmatic with paroxysms of violent coughing certain to develop this type of hernia. On the other hand, the asthenic individual with visceroptosis is not only the ideal candidate for the development of a direct inguinal hernia, but he is also more likely to have hemorrhoids and varicose veins than is a person of other body type. This suggests a congenital weakness of connective tissue throughout the body.

Direct inguinal hernia is a rarity in the female. This has been attributed to the flat, gynecoid pelvis of the female and a more even distribution of intra-abdominal pressures than in the male. While these anatomic facts may help to explain the low incidence of direct inguinal hernia in the female, it is also true that the posterior inguinal wall is almost always a heavy aponeuroticofascial plate in the female. Just why this is so, when as a rule the male has the better muscular development, cannot be explained, but it has been observed in the dissection of many cadavers and almost a thousand operations.

Irrespective of sex, body build, occupation or associated diseases that increase intra-abdominal pressure, the most important predisposing cause for the development of a direct inguinal hernia is a weak posterior inguinal wall. The posterior inguinal wall is the transversus abdominis aponeurosis with its investing fasciae and the strength of this wall is directly proportional to the number of aponeurotic fibers. The transversalis fascia is the innermost fascial layer and, by itself, has very little tensile strength. There is considerable variation in the strength of this layer even in those individuals who never develop a direct inguinal hernia.

There is also considerable variation in the internal oblique layer in the inguinal region which has been observed and recorded by a number of surgeons, but we now consider

this layer of secondary importance in the development of direct inguinal hernia.

Occasionally, direct external trauma may be the etiologic basis of a direct inguinal hernia and, certainly, injury to the posterior inguinal wall during the repair of an indirect inguinal hernia or a femoral hernia will cause a direct inguinal hernia. In this instance, it is usually a "diverticular" type of direct inguinal hernia (Fig. 5 d).

Incidence. This hernia represents about 20 per cent of the groin hernias and from 10 to 15 per cent of all parietal abdominal hernias. While it is readily seen that this is not as common as the indirect inguinal hernia, it is the direct inguinal hernia which has baffled surgeons in the past half century and it is the hernia that is most likely to recur. The conventional inguinal ligament hemiorrhaphies have been notably unsuccessful in repairing the direct inguinal hernia, recorded recurrence rates varying from 8 to 50 per cent.

Anatomy. The normal anatomy of the inguinofemoral region is presented in Figure 1, in which the number 2 represents the site of direct inguinal hernia. Whatever combination of factors operate to cause a direct inguinal hernia, the immediate cause is, of course, a dissolution of the integrity of the posterior inguinal wall.

The most common type of direct inguinal hernia is not an actual hole through the posterior inguinal wall, but a gradual attenuation of an intact but congenitally weak transversus abdominis aponeurosis. It is weak because of a deficient number of aponeurotic fibers. As the bulge of the hernia becomes larger and larger, the aponeurotic fibers are spread farther and farther apart. The fasciae, of which the innermost or transversalis fascia is the heaviest, stretch but maintain the continuity of this layer.

As the transversus abdominis layer gives way and bulges forward, the overlying internal oblique muscle is stretched and pushed superiorly. The spermatic cord, with its investing cremaster, usually remains below the bulge of the hernia. This is due to the disruption of the delicate fascial connection between the lower edge of the internal oblique and the cremaster. A strong musculoaponeurotic internal oblique layer may slow down the development of a direct inguinal hernia, but it cannot prevent it if the underlying transversus abdominis layer gives way. The significance of the so-called inguinal triangle in the causation of a direct inguinal hernia is certainly questionable.

However, this much is true—a deficient internal oblique layer in the inguinal region is frequently associated with a deficient transversus abdominis layer. The important point to understand is that the transversus abdominis aponeurosis with its investing fasciae is the key to the development of a direct inguinal hernia. If this layer is strong and intact, a direct inguinal hernia will not develop even though the internal oblique and external oblique layers are very weak or deficient. On the other hand, if the transversus abdominis layer begins to attenuate and bulge, the patient will develop a direct inguinal hernia in spite of a strong overlying internal oblique muscle.

The strength of the external oblique aponeurosis is of even less importance than the internal oblique muscle, for the developing hernia easily protrudes through this layer between the crura of the subcutaneous inguinal ring. This space between the aponeurotic crura of the external oblique aponeurosis is commonly referred to as a ring, actually it is a long triangle with the aponeurotic defect bridged by the innominate fascia. It is variable in strength, depending upon the number of intercrural fibers. When the hernia has passed through the external oblique layer, it enlarges in size in the subcutaneous fascia in the vicinity of the subcutaneous inguinal ring.

Hesselbach's triangle, bounded by the inguinal ligament, the inferior epigastric vessels and the lateral border of the rectus abdominis muscle, is a convenient descriptive area. Direct inguinal hernias must pass through this triangle. If a hernia occurs lateral to the inferior epigastric vessels, it is an indirect inguinal hernia. If a hernia occurs below the inguinal ligament, it is a femoral hernia. If a hernia occurs above the inferior epigastric vessels in the linea semilunaris, it is a Spiegel's hernia. Occasionally the sac of a direct inguinal hernia will straddle the obliterated hypogastric artery to form a pantaloon type of sac. However, this is a curiosity rather than of any particular significance and we place no emphasis upon whether the hernia has presented through the suprapubic fossa or the medial inguinal fossa.

The pathologic anatomy of the common type of direct inguinal hernia has been described rarely, one sees a direct inguinal hernia with a small neck and these are described as a diverticular type of direct inguinal hernia (Fig. 5 d). This hernia proceeds through the layers of the abdominal wall in

versus abdominis aponeurosis above, from abdominal inguinal ring to Cooper's ligament. Below, the glistening margin of Cooper's ligament must be seen medially and the edge of the anterior femoral sheath laterally. When these margins have been carefully dissected and the peritoneal sac excised, one is then ready to repair the hernia (Fig. 8 c).

After making the relaxing incision (Fig. 8 a and b), the strong cut edge of the transversus abdominis aponeurosis is sutured to Cooper's ligament from the pubic tubercle to within a few millimeters of the external iliac vein (Fig. 8 d). This maneuver not only reconstructs the posterior inguinal wall, but it re-establishes a normally broad insertion into Cooper's ligament and thus obviates the possibility of the development of a femoral hernia. It should be noted that the relaxing incision (Fig. 8 d) is now a considerable defect in the rectus sheath, protected behind by the rectus and pyramidalis muscles and their fasciae.

The next suture is the "transition" suture which approximates the edge of the transversus abdominis aponeurosis to the medial wall of the femoral sheath and pectineus muscle fascia. This suture is necessary to close the angle and permit the line of closure to come up from the level of Cooper's ligament to the more superficial level of the anterior femoral sheath. This distance is represented by the diameter of the external iliac vein.

The remaining defect is closed by suturing the transversus abdominis aponeurosis or in case the layer is muscular at this point, the transversalis fascia, to the anterior layer of the femoral sheath. This re-establishes the normal continuity of transversalis fascia into the anterior femoral sheath. This line of sutures is continued laterally until a snug abdominal inguinal ring is made just as it is done for the repair of the small- to medium-sized indirect inguinal hernia. The spermatic cord is dropped in against the new posterior inguinal wall and the external oblique aponeurosis closed over it (Fig. 8 e and f), thus re-establishing the obliquity of the inguinal canal. The subcutaneous inguinal ring is snugly closed.

DIRECT INGUINAL HERNIA

Definition. A direct inguinal hernia is one that passes through the posterior inguinal wall medial to the inferior epigastric vessels in the area bounded by Hesselbach's triangle.

Etiology. The etiologic basis of the direct inguinal hernia is both congenital and acquired. The acquired factor in the development of this hernia is easy to understand because it is operative in the development of all hernias and is due to increased intra-abdominal pressure from whatever causes. Sudden or abrupt increase in the intra-abdominal pressure is more effective in producing a hernia than is a gradual increase in pressure.

The congenital predisposition to the development of a direct inguinal hernia is undoubtedly the most important etiologic factor. The robust common laborer is not prone to develop a direct inguinal hernia, nor is the asthmatic with paroxysms of violent coughing certain to develop this type of hernia. On the other hand, the asthenic individual with visceroptosis is not only the ideal candidate for the development of a direct inguinal hernia, but he is also more likely to have hemorrhoids and varicose veins than is a person of other body type. This suggests a congenital weakness of connective tissue throughout the body.

Direct inguinal hernia is a rarity in the female. This has been attributed to the flat, gynecoid pelvis of the female and a more even distribution of intra-abdominal pressures than in the male. While these anatomic facts may help to explain the low incidence of direct inguinal hernia in the female, it is also true that the posterior inguinal wall is almost always a heavy aponeuroticofascial plate in the female. Just why this is so, when as a rule the male has the better muscular development, cannot be explained, but it has been observed in the dissection of many cadavers and almost a thousand operations.

Irrespective of sex, body build, occupation or associated diseases that increase intra-abdominal pressure, the most important predisposing cause for the development of a direct inguinal hernia is a weak posterior inguinal wall. The posterior inguinal wall is the transversus abdominis aponeurosis with its investing fasciae and the strength of this wall is directly proportional to the number of aponeurotic fibers. The transversalis fascia is the innermost fascial layer and, by itself, has very little tensile strength. There is considerable variation in the strength of this layer even in those individuals who never develop a direct inguinal hernia.

There is also considerable variation in the internal oblique layer in the inguinal region which has been observed and recorded by a number of surgeons, but we now consider

(indirect or femoral) sac which, of course, must be opened. This is known as the *Hoguet maneuver*.

Before beginning the reconstruction of the posterior inguinal wall (Fig. 8), it should be emphasized that the abdominal inguinal ring should be carefully explored from within to rule out the possibility of an incipient indirect inguinal hernia. Also, the contents of the femoral canal should be examined to rule out the possibility of a femoral hernia. In the obese patient, there is frequently a large amount of preperitoneal fat down in the femoral canal and this is always removed before beginning the hernia repair.

After disposing of the hernial sac, or sacs, as the case may be, the reconstruction of the posterior inguinal wall is performed exactly as described for the large indirect inguinal hernia (Fig. 8). In repairing the diverticular type of direct inguinal hernia, most of the posterior inguinal wall can be saved, but, even so, the relaxing incision is made to avoid any tension on the suture line.

In the large indirect inguinal hernia there is frequently a small triangle of posterior inguinal wall which remains in the angle between Cooper's ligament and the lateral border of the rectus muscle. This represents the inguinal falx in many cases and the attachment of the new posterior inguinal wall can begin here. In the large direct inguinal hernia, however, the suturing must begin at the pubic tubercle.

FEMORAL HERNIA

Definition. A femoral hernia is one which passes through the femoral ring and down the femoral canal to become subcutaneous in the fossa ovalis. It is simply a third variety of inguinal hernia.

Etiology. The etiologic basis of the femoral hernia is undoubtedly a combination of both congenital and acquired factors, however, we now consider the congenital predisposition to be the more important. The inclination of the female pelvis and increased intra-abdominal pressure due to pregnancy, or to any other cause, certainly play an etiologic role in the development of this hernia. Obesity, with an increase in fat in the preperitoneal layer and down into the femoral canal, may also play a role in the development of a femoral hernia, but a congenital peritoneal sac is not a factor.

The transverse diameter of the femoral ring in 100 consecutive cadavers was measured and found to vary from 5 mm. to 16

mm. An additional observation was that the larger the femoral ring, the narrower the attachment of the posterior inguinal wall into Cooper's ligament. Conversely, when the femoral ring was narrow in transverse diameter, the attachment of the posterior inguinal wall to Cooper's ligament was broad. In three of the cadavers a femoral hernia was present with a very broad femoral ring and a narrow insertion of the posterior inguinal wall into Cooper's ligament such as is illustrated in Figure 9 c. While this is not conclusive evidence of the etiologic basis of a femoral hernia, it is proof that there is considerable variation in the breadth of attachment of the posterior inguinal wall into Cooper's ligament with a corresponding inverse size of the femoral ring. A congenitally narrow insertion of the transversus abdominis aponeurosis (posterior inguinal wall) into Cooper's ligament may well be the principal cause of femoral hernia.

Incidence. The femoral hernia represents about 7.5 per cent of the groin hernias and between 3 and 4 per cent of all parietal abdominal hernias (Table 1). In our experience, it is four times more common in the female than in the male. It is most commonly seen in persons of middle age, but one of our patients with a bilateral femoral hernia was a two-month-old male infant.

Anatomy. The normal anatomy of the inguinofemoral region is presented in Figure 1. The number 3 represents the site of the femoral ring and is, of course, where a femoral hernia begins. There are several features of the normal anatomy of this region which are worthy of special mention. The broad attachment of the transversus abdominis aponeurosis (posterior inguinal wall) and the narrow femoral ring as shown in posterior view (Fig. 1 b) are the normal state and prevent the development of a femoral hernia. It should also be noted that the site of origin of a femoral hernia is as truly inguinal as either the indirect inguinal or the direct inguinal hernia—numbers 1 and 2 respectively (Fig. 1 a and b). The reason for emphasizing the inguinal origin of the femoral hernia is so the student will understand why the inguinal approach is the only rational route for the repair of this hernia.

Anatomy texts state that the medial wall of the femoral ring is the lacunar ligament. By comparing the anterior and posterior views (Fig. 1 a and b) it will be readily apparent that this is not true. The medial wall or margin of the femoral ring is the lateralmost attachment of the posterior in-

a similar manner and pushes out through the subcutaneous inguinal ring. It may also extend into the scrotum. This type of hernia has been seen following a previous repair of an indirect inguinal hernia and probably represents a tear in the posterior inguinal wall at the time of surgery. When it develops without previous surgery, it is probably on the basis of the lipoma theory of Cloquet, for on a number of occasions we have noted small protrusions of preperitoneal fat through the aponeurosis of the transversus abdominis while repairing an indirect inguinal hernia. When they were multiple, we have repaired the posterior inguinal wall as for a direct inguinal hernia. When single and small, we have simply reduced the fat and closed the tiny rent with a single fine silk suture.

Diagnosis. The diagnosis of a direct inguinal hernia is usually made with ease. The presence of a globular mass over the subcutaneous inguinal ring (Fig 5 a), which reduces readily with recumbency, immediately suggests the diagnosis. However, one cannot be certain without palpation. Compression over the abdominal inguinal ring does not prevent the appearance of the hernial bulge with standing or straining, as is the case in the small- to medium-sized indirect inguinal hernia. While this is also true in the case of a large indirect inguinal hernia, the large indirect variety is always completely scrotal. When a direct inguinal hernia extends into the scrotum, it is only into the upper scrotum and the spermatic cord and testis can be separated from the mass of the hernia.

With the examining finger pushing invaginated scrotal skin through the subcutaneous inguinal ring, it is readily apparent that the posterior inguinal wall is gone. When the patient strains against the examining finger, there is no feeling of resistance and, in spite of the muscular effort, the finger can palpate Cooper's ligament on the superior pubic ramus with ease and even feel the posterior aspect of the pubic bone.

The inexperienced may confuse a femoral hernia with a direct inguinal hernia, especially when the femoral hernia turns back upon itself and comes to lie over the inguinal ligament near the pubic tubercle. Careful digital examination, however, will demonstrate the neck of the sac and a portion of the body of the sac lying below the inguinal ligament. In the case of a direct inguinal hernia, the hernial mass is principally above the inguinal ligament. Other patho-

logic conditions in the groin are quite readily differentiated from the direct inguinal hernia.

The typical direct inguinal hernia reduces with ease and does not become incarcerated. This is due to the large size of the ring or defect in the posterior inguinal wall. For this reason, this hernia is usually painless although it may cause a heavy feeling or be described by the patient as a dragging sensation. The obese patient is the most likely to complain of discomfort because of the pressure of a large quantity of preperitoneal fat pushing through the defect. There may be enough pressure to cause urinary symptoms, because the urinary bladder invariably forms a portion of the medial wall of the hernial sac. The uncommon diverticular type of direct inguinal hernia not only frequently incarcerates but may strangulate, this is due to the small rigid ring through the posterior inguinal wall. Whereas the direct inguinal hernia with a large defect will not get the patient into serious difficulty and operation is not urgent, the diverticular type is potentially dangerous and should be corrected surgically without delay.

Treatment. The rational repair of a direct inguinal hernia must include the replacement of the destroyed posterior inguinal wall. Various methods of accomplishing this have been discussed under the treatment of the large indirect inguinal hernia and the same principles apply to the direct inguinal hernia. In general, the only difference between the two hernias, as regards the technique of repair, is the different management of the peritoneal sac and the fact that the direct inguinal hernia usually destroys more of the posterior inguinal wall. Whereas dissection and high ligation of the peritoneal sac are mandatory in the operation for indirect inguinal hernia, the diffuse bulging of the direct inguinal hernial sac with its broad neck does not necessitate even opening the peritoneum. The sac is simply pushed in and held with a retractor while the posterior wall is reconstructed. However, in the rare diverticular type of direct inguinal hernia, or if there is any question about adherent viscera to the larger sac, the sac is always opened, but it must be remembered that the urinary bladder forms its medial wall. In the event that there is an associated indirect inguinal or a femoral hernia, the excess of peritoneum in the direct inguinal hernial sac is pulled into the other

guinal wall into Cooper's ligament. The lacunar ligament lies more medially by at least 1 cm. and in a more superficial plane. It should also be noted that the inguinal and lacunar ligaments cannot be seen in a posterior view of the inguinal region. Those figures commonly used in textbooks which show the inguinal and lacunar ligaments in a posterior view are artifactual in that the posterior inguinal wall has either been removed or else it is shown inserting into the inguinal ligament. In the presence of a femoral hernia, the medial wall of the neck of the hernia does abut against the lacunar ligament (Fig. 9 b and c), but this is a pathologic state. Furthermore, the inguinal and lacunar ligaments are not the primary ring of the hernial defect, although they are the final restraining structures. When it is necessary to cut the inguinal ligament to reduce a femoral hernia, it can be plainly seen that the true ring of the femoral hernial defect is the femoral sheath and the aponeuroticofascial fibers of the posterior inguinal wall en route to an insertion into Cooper's ligament (Fig. 9 b and c).

Irrespective of the number of factors which combine to permit the development of a femoral hernia, several progressive changes take place as the hernia enlarges. This hernia begins as a plug of fat in the femoral canal which gradually enlarges and eventually pulls a diverticulum of peritoneum through the femoral ring and down into the femoral canal. As more and more peritoneum pushes out through the femoral ring, the urinary bladder invariably becomes a part of the medial wall of the hernial mass. The hernial sac characteristically has a liberal covering of preperitoneal fat and the bladder on the medial wall is not immediately apparent (Fig. 10 a and b). The course of the developing hernia is down the femoral canal where it is forced out of the fossa ovalis by the vessels and the deep fascia. It becomes subcutaneous, pushing the cribriform fascia ahead of it, and at this point the hernia is femoral in location and appears as illustrated in Figure 9 a. As the hernia increases further in size, it turns cephalad and may eventually lie in part above the level of the inguinal ligament.

The most important anatomic change takes place at the femoral ring, for as the ring enlarges it pushes the lateral attachment of the transversus abdominis aponeurosis into Cooper's ligament medially, thereby progressively narrowing this tendinous insertion (Fig. 9 c) until the more super-

ficially placed lacunar ligament is reached. This is the final and greatest size of the femoral ring. It is a rigid and unyielding ring and accounts for the high incidence of incarceration and strangulation in this type of hernia. The other boundaries of the femoral ring are correctly recorded in all textbooks of anatomy and need not be elaborated upon, except to state that the immediate anterior boundary of the femoral ring in both normal anatomy and in the presence of a femoral hernia is the anterior femoral sheath, reinforced more superficially by the inguinal ligament. The direct inguinal hernia and the large indirect inguinal hernia destroy the posterior inguinal wall completely (Fig. 4 c and 5 c). It should be noted that a femoral hernia destroys the lateral half of the inferior portion of the posterior inguinal wall (Fig. 9 c).

Diagnosis. The diagnosis of a femoral hernia is usually not difficult, but to superficial inspection a femoral hernia may closely resemble a direct inguinal hernia when it curves upward over the inguinal ligament. After the pubic tubercle and inguinal ligament are identified, the neck of the hernia can be felt below the inguinal ligament. In the slender patient, palpation is easy, but in the obese female it may be difficult for the palpating fingers to become oriented. A direct inguinal hernia reduces with ease, the diverticular type excepted, but a femoral hernia is usually incarcerated. An indirect inguinal hernia that just protrudes through the subcutaneous inguinal ring may superficially resemble a femoral hernia, but careful palpation will serve to differentiate the two. Varicocele of the upper scrotum or labia and a saphenous vein varix may slightly resemble a femoral hernia and it must be remembered that a saccular varix in this location also imparts an impulse on coughing. An enlarged subinguinal lymph node in the fossa ovalis, especially in the presence of lymphadenitis or metastatic neoplasm, may exactly mimic an incarcerated or strangulated femoral hernia. When this differential diagnosis presents itself, a careful search should be made for wounds or other inflammatory lesions on the corresponding lower extremity, genitalia and rectum. A very trivial inflammatory lesion between the toes, frequently associated with a fungus infection, can cause severe femoral lymphadenitis, a small fissure in ano can do the same. Subinguinal lymphadenitis and a strangulated femoral hernia are both exquisitely

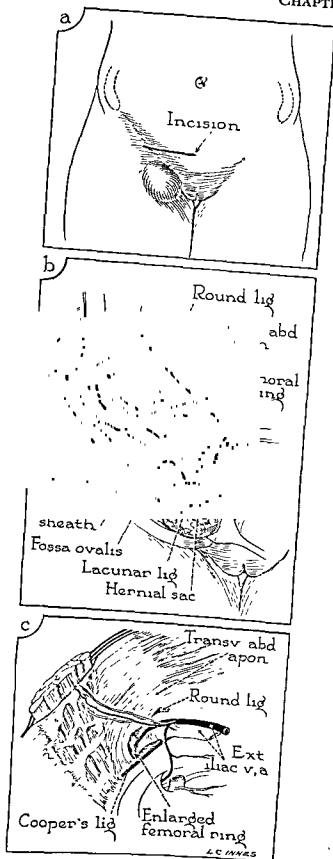

Fig 9

ligament to expose the neck of the femoral hernia

Figures 9, 10, and c.

small retractor is used to elevate the inguinal ligament so that the constricting ring of the femoral sheath may be cut. For most femoral hernias this maneuver suffices for the reduction of the hernia. However, if by a combination of gentle traction above and pressure from below the hernia cannot be reduced, the lacunar portion of the inguinal ligament is cut part way through or, if necessary, completely divided. After the sac has been pulled out of the femoral canal, it is in the position of a diverticular direct inguinal hernia (Fig. 10 b). A femoral hernial sac must always be opened because it frequently contains adherent omentum or viscera, the operator bearing in mind that the urinary bladder is part of the medial wall of the fatty envelope which surrounds the peritoneal sac (Fig. 10 b). With the sac opened, one should pass a finger into the abdominal cavity and feel for the opening of an indirect inguinal hernia sac, combining this with direct inspection of the abdominal inguinal ring. The inside of the abdominal inguinal ring can be easily inspected by retraction (Fig. 10 c), if for no other reason than to familiarize oneself with the construction of a normal abdominal inguinal ring. The hernial sac is next ligated at its base and the excess excised, again remembering the position of the urinary bladder.

The hernia is then repaired by suturing the cut edge of the posterior inguinal wall to Cooper's ligament up to within a few millimeters of the vein (Fig. 10 d). This not only reconstructs a normally attached posterior inguinal wall but closes the femoral ring and thus corrects the defect which permitted the hernia to develop. The relaxing incision is not necessary. The transition suture (Fig. 10 d) picks up the fragmented end of the anterior femoral sheath and a liberal bite of the pectineus muscle fascia and approximates them to the posterior inguinal wall. This suture not only re-establishes the medial wall of the femoral sheath but is necessary to close the angle between the level of Cooper's ligament and the more superficial anterior layer of the femoral sheath. The operation is completed by approximating the transversalis fascia to the anterior layer of the femoral sheath (Fig. 10 d). The external oblique aponeurosis is closed over the cord or round ligament and the subcutaneous fascia and skin are sutured as for the other groin hernias.

SLIDING HERNIA

The sliding hernia is not a special type of hernia but rather represents a complication

in the management of the hernial sac in several types of hernias. A sliding hernia is most commonly encountered in groin hernias. The entity, sliding hernia, is most easily explained by describing the mechanism of its development. It occurs most commonly in the indirect inguinal hernia because this is the most common of all hernias, but it should be understood that there is a sliding hernia of the urinary bladder in almost all femoral hernias (Fig. 11 c) and direct inguinal hernias.

In the early stages of an indirect inguinal hernia, the hernial sac consists solely of the congenital diverticulum of peritoneum and the hernia may enlarge considerably by stretching of the sac. However, when the hernia is of long standing and because of the pressure of its contents, further enlargement of the hernial sac comes from a sliding downward of parietal peritoneum. The peritoneum proximal to the orifice of the hernia is least tightly fixed in the iliac fossa. As this peritoneum is pulled into the hernial sac, the cecum (Fig. 11 a) or sigmoid colon (Fig. 11 b), with a short or absent mesentery, becomes part of the posterolateral wall of the hernial sac. The bowel is outside the lumen of the hernial sac and presents an additional problem in the high ligation of the sac. The peritoneum cannot be dissected off the viscus because it is visceral peritoneum. Therefore the viscus is simply cut out of the side of the hernial sac which, of course, leaves a rent in the wall of the sac. The management of this is a technical problem which is easily handled. Care must be exercised in dissecting the viscus away from the hernial sac because of the mesenteric vessels.

Another mechanism for the development of a sliding type of hernia is seen in incomplete descent of the testis or in the abnormal descent of an ovary into the inguinal canal (Fig. 11 d). In the former, this is simply an arrest in the normal mechanism of the descent of the testis into the scrotum. In the latter, the mechanism is the same although it is an abnormality for the ovary to descend into the inguinal canal. When either of these two abnormalities exists, there is invariably an indirect inguinal hernia associated, although the peritoneal sac may not contain a viscus.

In a diaphragmatic hernia, a variety of retroperitoneal viscera may "slide" into the thoracic cavity. We have observed the spleen, liver, kidney, adrenal and tail of pancreas in a left-sided diaphragmatic hernia, in addition to the several hollow viscera.

tender, which makes diagnostic palpation more difficult.

Occasionally, premonitory urinary symptoms such as dysuria, hematuria and frequency will precede any palpable evidence of a femoral hernia by months. This is due to a knuckle of the urinary bladder being caught during the early development of the hernia. A Littre's hernia, in which only a portion of the circumference of the small intestine may be incarcerated or strangulated in the ring, is especially common in a femoral hernia. A femoral hernia should always come to mind when one is confronted with a case of unexplained intestinal obstruction. The appendix, ovary or Meckel's diverticulum is occasionally found in a femoral hernia. In this event, it is usually strangulation of the contained viscus which brings the patient very promptly to the physician.

Treatment. The variety of operations described for the repair of a femoral hernia almost equals the number recorded for the repair of indirect and direct inguinal hernias and, in like measure, reflects basic misunderstanding of the pathologic anatomy. To review the many operations for femoral hernia would only serve to cause confusion and, as a matter of fact, the majority of these operations are better left unlearned except for those interested in the history of surgery in this region. The femoral approach is anatomically unsound. The many techniques in which an attempt is made to suture the inguinal ligament to Cooper's ligament even by the inguinal approach are likewise an anatomic mistake. The inguinal ligament has mobility in a cephalad direction, but it is a taut cord when attempts are made to displace it posteriorly and approximate it to Cooper's ligament as far laterally as the femoral vein. In any event, suturing the inguinal ligament to Cooper's ligament by either the femoral or the inguinal approach is an unanatomic and unsound surgical procedure, for the defect is more deeply placed. The defect in a femoral hernia, irrespective of the causative factors, is a narrowing of the insertion of the transversus abdominis aponeurosis and its fused fasciae (posterior inguinal wall) into Cooper's ligament. The repair of a femoral hernia, after removal of the hernial sac, is correctly accomplished by broadening this insertion so as to obliterate the femoral ring. This concept was correctly understood many years ago by Lotheissen and in recent years by others. A femoral hernioplasty is one of

the nicest operations in the entire field of surgical anatomy when the surgeon understands both the normal and pathologic anatomy of this region. The aponuroticofascial layers are invariably strong and, in the absence of associated inguinal hernias, it offers the surgeon an unparalleled opportunity to observe normal inguinal anatomy.

The skin incision for a femoral hernioplasty is the same as that for the other inguinal hernias (Fig. 9 a). The external oblique aponeurosis is incised and the inguinal region exposed by elevating the spermatic cord or the round ligament exactly as for an inguinal hernioplasty (Fig. 9 b). At this point, the posterior inguinal wall and the abdominal inguinal ring are carefully inspected for associated hernias. The abdominal inguinal ring is inspected again later from within. The hernial sac is shelled out of its subcutaneous femoral position (Fig. 10 a) until the neck of the sac is reached. If there is any question of non-viable contents, the sac should be opened at this time for careful inspection before releasing the constriction of the femoral ring. It is a disquieting experience to have a loop of bowel disappear into the abdominal cavity before it is examined. Should this happen, one is then obliged to inspect the adjacent colon and all of the small bowel with a mesentery sufficiently long to permit its entrance into the hernial sac. This precaution, as regards releasing the constriction at the neck of the hernia, applies to all types of hernias with questionably strangulated contents.

An incision is next made in the femoral sheath immediately above the inguinal ligament and carried over the bulge of the neck of the hernia and down to Cooper's ligament (Fig. 10 a). This allows access to the neck of the hernia and, later, for the repair of the hernia. When this incision is made, one has, of course, entered the preperitoneal space and the next step is to separate the neck of the hernia from the external iliac vein. This is easily accomplished, as there is always a nice plane of cleavage due to the areolar tissue surrounding the vein. Tributary blood vessels must be searched for carefully, doubly ligated and cut. This is especially true when an aberrant obturator artery has been pushed forward by the hernia. Aberrant obturator veins are commonly seen. The small artery and vein to the pyramidalis muscle, which course along the edge of Cooper's ligament, are invariably present.

On the right side, the liver, adrenal gland and even the superior pole of a kidney have been found in a posterior diaphragmatic hernia through the pleuropertoneal foramen of Bochdalek. On one occasion a portion of the right adrenal was inadvertently removed in the repair of this hernia before the structure was recognized.

COMPARISON OF SEVERAL METHODS OF INGUINAL HERNIOPLASTY

Although we are opposed to the use of the inguinal ligament in the repair of any groin hernia, the approximation of the "conjoined tendon" to the "shelving border" of Poupart's ligament is so widely accepted that every surgeon should be conversant with certain operations which use the inguinal ligament as the anchoring structure. Although the number of these operations recorded is in excess of seventy, they are all variations of three classic procedures and the difference between these three operations is the position in which the spermatic cord is placed. Figure 12 was prepared in

semi-diagrammatic form to show the fundamental features of these three operations and then, for comparison, what we believe should constitute an adequate hernia repair.

Before studying these diagrams, reference should be made to Figure 1 to become familiar with the normal anatomy of the inguinal region. It is readily seen that the posterior inguinal wall does not insert into, or attach to, the inguinal ligament, except that near the pubic tubercle the lacunar portion of the inguinal ligament and the posterior inguinal wall have a common insertion into Cooper's ligament. It is upon this anatomic fact, plus the inadequacy of the inguinal ligament as a substitute, that we believe the principles for the repair of the groin hernias should be based. Should it quite justifiably be pointed out that the inguinal ligament hernioplasty has stood the test of time with a very favorable cure rate, it should be clearly understood that the majority of inguinal hernia operations (Table 1) are for the relatively small indirect inguinal hernia, where success will attend al-

a, b and c, with e). All of the diagrams in Figure 12 a, b, c and e represent techniques for the repair of the small indirect inguinal hernia and in all of these procedures the posterior inguinal wall is perfectly intact. The crux of the matter is this: when the pathologic condition is simply a small, congenital, indirect inguinal hernial sac with only slight dilatation of the abdominal inguinal ring, suturing of the posterior inguinal wall to Poupart's ligament (Fig. 12 a, b and c) is unnecessary. Not only is it unnecessary, but there is danger of tearing this wall with subsequent herniation through the defect. Very adequate repair of this most common of all hernias is illustrated in Figure 12 e and consists of simply tightening the abdominal inguinal ring to normal size by suturing the transversalis fascia to the anterior layer of the femoral sheath. In children, one suture frequently suffices and not three as depicted. It should also be noted that the spermatic cord (Fig. 12 e) is in the normal position, as it is in the Bassini operation (Fig. 12 a).

For this comparative study, the Bassini operation was selected as an example of inguinal ligament hernioplasty for the repair of a direct inguinal hernia (Fig. 12 d). Whereas it was pointed out that suturing the posterior inguinal wall to the inguinal ligament was unnecessary in the small indirect inguinal hernia, it is equally important to note that it is anatomically incorrect to suture the posterior inguinal wall to the inguinal ligament in a direct inguinal hernia. When the posterior inguinal wall is destroyed, as in the case of a direct or a large indirect inguinal hernia, the reconstruction of a new posterior inguinal wall should include the attachment of this wall to its normal insertion, which is, of course, Cooper's ligament (Fig. 12 f). The normal attachment of the posterior inguinal wall is accurately shown in Figure 1 a and b, and diagrammatically demonstrated in Figure 12 a, b, c and e. When the inguinal ligament is used as the anchoring structure in patients in whom the posterior inguinal wall has been destroyed, it leaves an anatomic fault (Fig. 12 d, double arrow) which is, in effect, a large femoral hernial ring. Some recurrent hernias are of this variety. More important, the parallel and easily separated fibers of the inguinal ligament are not a suitable anchoring structure for the repair of the large groin hernias. The normal insertion (Cooper's ligament) is readily available and is a very strong, unyielding structure.

HERNIAS OF THE LINEA ALBA AND THE LINEA SEMILUNARIS

These hernias are quite naturally grouped together since they have many features in common and occur along lines of aponeurotic fusion. The principles involved in their surgical repair are also very similar. Figure 13 is a posterior view of the abdominal wall showing the aponeurotic defect in an epigastric, an adult umbilical and a semilunar (Spiegel's) hernia. Opposite each hernia and indicated by the arrow is a transverse section through the abdominal wall to show the relationships of the various layers from skin to peritoneum.

UMBILICAL HERNIA

Definition. An umbilical hernia is one that passes through the umbilical ring and includes three types: omphalocele, or fetal umbilical hernia (Fig. 14 a), which is a failure of a portion of the intestinal tract to return to the abdominal cavity during early fetal development; infantile umbilical hernia (Fig. 14 b), which is a failure of the umbilical ring to obliterate; adult umbilical hernia (Fig. 14 c), which is the acquired dilatation of an imperfectly closed umbilical ring.

Etiology. Omphalocele is due to the failure of complete return of the eviscerated organs to the abdominal cavity. This, in turn, is due to a spatial problem in that the abdominal cavity has not enlarged enough to accept all of the intestinal tract that has grown and rotated during its extrusion into the base of the umbilical cord. The size of an omphalocele varies from a single loop of small intestine to a large sac containing most of the abdominal viscera. An infantile umbilical hernia is due to faulty closure of the umbilicus as the umbilical vessels become obliterated. There seems to be a familial tendency in that several children in one family will have this type of hernia while none of the children in an equally large family presents this abnormality. From a racial standpoint, this hernia is much more common in members of the Negro race than in those of the white race. An adult umbilical hernia has a twofold etiologic basis in that there must be a congenital defect in the umbilical scar, with the superimposed element of increased intra-abdominal pressure. A completely closed umbilicus presents a very dense interdigitation of aponeurotic fibers scarred together by the healing of the umbilical wound. No degree of intra-

most any operation that includes high ligation and excision of the peritoneal hernial sac. The large indirect inguinal hernia, the direct inguinal hernia and the femoral hernia have always had a high recurrence rate with inguinal ligament types of repair, but the preponderance of small indirect inguinal hernias in any series has permitted a favorable and honest report of success. In the future, the statistical analysis of the results in a given series of hernioplasties should break down the groin hernias into their respective types so that a true picture of hernia recurrence may be obtained.

The semidiagrammatic drawings (Fig. 12) represent a posterior view of the inguinal region in several types of hernioplasty, with the medial portion of the posterior inguinal wall and the rectus abdominis muscle cut away. To the left of each figure, and between the two bottom figures, is a diagrammatic sagittal section at the level of the cut-back in the main figure to show the attachment of the layers and the relative position of the spermatic cord. The small crosses on the inguinal-lacunar ligament (Fig. 12 a, b, c and d) and on Cooper's ligament (Fig. 12 f) represent the continuation of the line of sutures to the pubic tubercle. The peritoneum is not shown for it is presumed that the hernial sac has been adequately resected in all instances.

Credit for the first satisfactory inguinal hernia operation properly belongs to H. O. Marcy of this country, as pointed out by Zimmerman and Anson. However, the first satisfactory hernia operation to be widely accepted was described in 1889 by Edoardo Bassini. In addition to dissection and high ligation of the sac, the lower edge of the internal oblique muscle and the posterior inguinal wall (conjoined tendon) were sutured to the inguinal ligament from the pubic tubercle to the abdominal inguinal ring. The spermatic cord was placed against this wall and the external oblique aponeurosis closed over the cord, reconstructing the subcutaneous inguinal ring in its normal location (Fig. 12 a). In a general way, this operation is the most rational because it reinforces the posterior inguinal wall and re-establishes the obliquity of the inguinal canal. Through the years, the majority of operations have been based upon this principle with minor variations ad infinitum.

Almost simultaneously, William S. Halsted, in this country in 1889, described an operation which has subsequently become known as the Halsted I (Fig. 12 b). Hal-

sted subsequently abandoned this technique and adopted a procedure essentially similar to the Bassini operation. In this country, it became known as the Halsted II. The Halsted I operation also included high ligation of the peritoneal sac and the approximation of the conjoined tendon to Poupart's ligament. With the idea of making a stronger posterior inguinal wall, the external oblique aponeurosis was closed deep to the cord, usually by plication, thus obliterating the inguinal canal. This procedure superimposes the subcutaneous inguinal ring upon the abdominal inguinal ring and leaves the spermatic cord in the subcutaneous fascia (Fig. 12 b). Although this principle is still widely used, it is faulty because it destroys the obliquity of the inguinal canal and the so-called shutter action of the muscles. It is attended by a high incidence of recurrence directly through the superimposed rings.

The third operation of classic significance is known as the Ferguson procedure, although it was described many years before by Bull and Coley. Originally it was used to reinforce a supposed inadequacy in the origin of the internal oblique and transversus abdominis muscles from the inguinal ligament. The inguinal portions of these muscles do not originate from the inguinal ligament as described, but from the fascia lata immediately beneath. In later years this procedure has been advocated in patients with cryptorchidism to gain additional length of the spermatic cord. The procedure represents a third alternative for the placement of the spermatic cord (Fig. 12 c). After ligation of the hernial sac, the cord is pushed inward and the conjoined tendon sutured to Poupart's ligament over the cord. The external oblique aponeurosis is then closed over this wall. This technique places the abdominal inguinal ring just lateral to the pubic tubercle and immediately beneath the subcutaneous inguinal ring. The Ferguson operation also destroys the obliquity of the inguinal canal with its shutter action and is attended by a high incidence of recurrence just lateral to the pubic tubercle which is in effect a direct inguinal hernia.

If the Bassini, the Halsted I and the Ferguson operations (Fig. 12 a, b and c) are carefully compared, it will be apparent that the approximation of the layers is identical and that the difference lies in the placement of the spermatic cord. Of the three, it is our opinion that the Bassini operation is the best. However, at this point a very important fact should be observed (Fig. 12, compare

abdominal pressure will disrupt such an umbilicus. However, a small defect in the umbilicus, with increased intra-abdominal pressure due to such conditions as pregnancy, intestinal obstruction, chronic cough and ascites, can cause an adult umbilical hernia without antecedent history of such a hernia. Obesity is associated with an umbilical hernia so commonly in the adult as to

congenital anomaly reported to occur about once in every 5000 to 6000 births. Infantile umbilical hernia is of very common occurrence, especially in members of the Negro race, with the reported incidence varying from 1 to 10 per cent in white children and up to as high as 80 per cent in Negro children. Adult umbilical hernia is not uncommon but is less frequently seen than the infantile type. An accurate incidence of infantile and adult umbilical hernias is difficult to determine because, unless these hernias are symptomatic, patients will frequently not consult a physician. However, these two types of umbilical hernias compose a substantial proportion of any series of hernias for which operations are performed (Table 1, average 9.4 per cent).

Anatomy. Normally at birth the umbilical defect is small and just accommodates the umbilical arteries, the umbilical vein, the urachus and a small amount of embryonic connective tissue. After ligation of the umbilical cord, the blood vessels become thrombosed back to their nearest collateral and eventually become fibrous cords. The umbilical vein becomes the round ligament of the liver lying in the free margin of the falciform ligament of the liver. The umbilical arteries become the obliterated hypogastric arteries which elevate the peritoneum into the lateral umbilical folds. The urachus obliterates and becomes the middle umbilical ligament over which the peritoneum folds as the middle umbilical fold.

The defunctionalized umbilical vessels and urachus apparently cannot keep the umbilicus open or, stated another way, it is possibly the pressure of the circulating blood in these vessels which prevents the umbilicus from closing prematurely with disastrous results for the fetus. It is also likely that the contraction of the abdominal musculature after birth exerts a shutter-like action at the umbilicus. In any event, irrespective of where the cord is ligated, the slough ex-

posed to the aponeurotic aperture and, in studying the disposition of the aponeurotic fibers about the umbilicus (Fig. 13), it is easy to understand how lateral muscle pull tends to close the umbilicus and tightly constrict the structures passing through it. When the cord sloughs, a granulating defect is left which adds scar tissue to the approximated aponeurotic fibers and forms a very dense composite wall that no amount of pressure will disrupt to result in an umbilical hernia. The umbilical skin grows in circumferentially under the umbilical eschar which accounts for the fixation of the umbilical skin to the linea alba.

Aberrations in this pattern of closure result in umbilical herniation. First, is the fetal umbilical hernia (Fig. 14 a), or omphalocele, in which the defect cannot close because one or more viscera have been protruding through the umbilicus since the sixth week of intrauterine life and prevent normal development of the aponeurotic elements of the lateral musculature. The size of this defect depends upon the bulk of the protruding viscera. Ordinarily, the viscera which protruded into the umbilical cord have returned by the tenth or eleventh week of intrauterine life, have grown considerably and have completed the rotation that brings the transverse colon over the superior mesenteric vessels. When the viscera fail to return completely into the abdominal cavity, it is because the cavity has not enlarged sufficiently to receive them. When a child is born with an omphalocele, a situation exists which is not present in any other hernia and it demands prompt correction. The viscera lying in the umbilical cord are not covered with skin but by a very thin, translucent membrane which consists of fused peritoneum and amniotic membrane. With exposure to air, it very rapidly dries and becomes necrotic so that peritonitis supervenes in a matter of hours.

The second type of umbilical hernia is the infantile umbilical hernia (Fig. 14 b) which makes its appearance either shortly after birth or in the first year or two of life, usually following an episode of increased intra-abdominal pressure, which can be an almost hourly event attending crying, straining and coughing. This type of hernia is covered with the everted umbilical skin. The skin at the apex of the umbilical dimple is densely adherent to the linea alba at the umbilicus. On the posterior aspect of the umbilicus the peritoneum is equally adherent. Therefore there is peritoneum, umbilical scar and skin without the interposition of adipose tissue

Figure 13 Posterior view of the anterior abdominal wall showing the musculoaponeurotic defects in an epigastric, an umbilical and a semilunar (Spiegel's) hernia. On the left are transverse sections through these hernial defects with the peritoneum and preperitoneal connective tissue added.

Figure 14 The appearance of the three types of umbilical hernias in anterior view and sagittal section. a, Fetal umbilical hernia or omphalocele b, Infantile umbilical hernia c, Adult umbilical hernia

toms, vague upper gastrointestinal symptoms due to traction on the omentum are common. As the hernia enlarges and loops of intestine enter the sac, partial intestinal obstruction with its associated symptoms appears. The transverse colon is usually the first hollow viscus to enter the hernia and is literally pulled in by the omentum. Strangulation of the contents of this hernia is very common because of the rigidity of the aponeurotic ring. Although this hernia is always unilocular, rents in the incarcerated omentum make secondary constricting apertures which greatly aggravate the symptoms and may well be the precipitating element in strangulation.

Treatment. The fetal umbilical hernia, or omphalocele, demands immediate surgical treatment, which means within the first few hours after birth. In the small omphalocele, this presents no special problem because, properly managed, the infant withstands an operation well. The loop of intestine is easily reduced because there is no distention of the intestine with food and air. The repair of the aponeurotic defect is the same as for the infantile umbilical hernia and need not be elaborated upon. The only difference is that no attempt is made to fashion an umbilical dimple out of the cuff of periumbilical skin. This cuff of skin is excised as an ellipsoidal segment and removed with the omphalocele sac (Fig. 14 a). For the management of the large omphalocele, or when the abdominal cavity is too small to comfortably accommodate the exteriorized viscera, the two-stage procedure of Gross is certainly the operation of choice.

The infantile umbilical hernia which appears shortly after birth does not need immediate surgical correction unless it becomes incarcerated, but this is a rare occurrence. Many of these hernias gradually disappear without any treatment owing to the gradual constriction of the defect by aponeurotic pull across the midline. In most instances, it is wise to keep the hernia reduced, either by the use of tape and a block of sponge rubber or by the method of infolding the adjacent skin as described by Gross. Any hard object such as a coin, button or marble should not be forced into the defect to keep the hernia reduced. A mechanical truss will not stay in place on a squirming infant. After the infant is approximately one year of age, taping the hernia is not effective and should be abandoned. If the hernia persists and is symptomatic after one year, it should be repaired. If it persists and is asymptomatic, an elective operation can be performed at any time. A large umbilical hernia in an infant should be repaired without delay.

The infantile umbilical hernia is repaired quite simply through a small transverse incision either just above or just below the umbilicus (Fig. 14 b). The umbilical skin is carefully dissected off the hernial sac and the sac dissected free through the aponeurotic defect. After the sac is opened to be sure that there are no incarcerated contents, the neck of the sac is ligated with a fine silk suture (Fig. 15 a). The defect is then closed in the transverse plane as illustrated in Figure 15 b. Although closure of this defect in the vertical plane has given good results in reported series, the transverse

and this accounts for the thin covering of these hernias when a defect persists in the umbilicus. Between the peritoneum of the hernial sac and the everted umbilical skin, there is only the thinnest of areolar tissue layers. The healing of the umbilicus is essentially the same in all infants with approximately the same amount of scar tissue incident to the healing process. The arrangement that permits this hernia to develop must, therefore, be an abnormality in the disposition of the aponeurotic fibers about the fetal umbilical defect. When muscle fibers contract, the corresponding aponeurotic fibers attempt to make a straight line from their point of insertion (Fig 18 c and d). The interdigitation of aponeurotic fibers about the umbilicus in three different planes, corresponding to their origin from the muscle fibers of the two obliques and one transverse anterolateral abdominal muscle, would tend to close effectively an aperture at the umbilicus. The protrusion of extraperitoneal fat is not an etiologic factor here, as it is in epigastric and other hernias, neither are there perforating blood vessels other than the fetal ones. The foregoing is not advanced as the absolute cause of this type of hernia, but, like many others, through the years we have attempted to reach a rational explanation of the enigma of why some infants do, and others do not, develop this hernia.

The third type of umbilical hernia is the adult umbilical hernia (Fig. 14 c). It is most commonly seen in persons of middle age, although not uncommonly in the obese multiparous female in her early twenties. Although increased intra-abdominal pressure is the precipitating cause of this hernia, the underlying etiologic condition is the persistence of a small defect from birth. As has been mentioned, the normally healed umbilicus will not develop a hernia. Small asymptomatic defects in the umbilicus, without a sac and without an impulse, are a fairly common finding in routine physical examinations. Another common finding is a small pea-sized irreducible and nontender lump in the umbilical dimple. This is incarcerated omentum, as can be demonstrated by intra-abdominal exploration at the time of celiotomy performed for some other reason.

With a small defect containing a tag of omentum, it is not difficult to see that this is the entering wedge for the development of a typical umbilical hernia in the adult. Increased intra-abdominal pressure from whatever cause gradually pushes more and more

omentum into the defect and, eventually, transverse colon enters the hernia as the first viscus. Pregnancy is the most common etiologic factor. Obesity is an important contributing factor and ascitic fluid in an umbilical hernial sac may be the first indication that the patient has a hernia. Once established, the hernia progressively enlarges in size unless the cause of the pressure is relieved. It is not uncommon for an umbilical hernia to decrease in size and become asymptomatic after a woman has delivered. In this event, the woman with a previously painful umbilical hernia may refuse operation only to find that with the next pregnancy the hernia becomes larger and more symptomatic.

Diagnosis. The diagnosis of an umbilical hernia presents no problem even to the uninitiated, although occasionally a very small defect strangulating a tiny tag of omentum will be exquisitely tender and be difficult to feel in an obese patient. An epigastric hernia occasionally occurs just above the umbilicus, but, although it may bulge into the umbilical skin from above, the apex of the umbilical dimple remains fixed to the linea alba. Confusion on this differential point is of small consequence for the principles of repair of the aponeurotic defect are identical. A sebaceous cyst or urachal cyst may superficially resemble an umbilical hernia.

Symptomatically, the omphalocele does not bother the newborn until peritonitis supervenes and this may be within a few hours. If the omphalocele sac is torn during delivery, peritonitis begins at once. An omphalocele should be immediately apparent, although a small loop of intestine may not be noticed unless the base of the umbilical cord is carefully inspected. To include a loop of small intestine in the ligature of the umbilical cord is to give the infant a strangulating obstruction with its attendant mortality.

The infantile umbilical hernia rarely incarcerates and is rarely symptomatic in the first year of life, although larger hernias in older children cause local pain and digestive disturbances. The mother invariably makes the diagnosis before the doctor sees the child.

The fully developed adult umbilical hernia is usually painful, frequently incarcerated and danger of strangulation is imminent. Omentum is usually the first organ to enter the hernial sac and, because of repeated trauma, shortly becomes adherent to the sac (incarcerated). At this stage, even though there are no significant local symp-

woven pattern closely covered by the fasciae which has led surgeons to refer to the sheaths loosely as "fasciae" and to cut them indiscriminately. The aponeurotic fibers in the rectus sheaths maintain their various directions as they mingle in their mutual insertion at the midline and form the linea alba. By careful dissection, and sometimes with the use of a magnifying glass, it is possible to trace a given aponeurotic fiber through the linea alba into the opposite rectus sheath. It is undoubtedly this characteristic which led some of the earlier anatomists to consider the six anterolateral abdominal muscles as three digastric muscles. This, at least, serves a useful purpose from a teaching standpoint to remind the surgeon that midline hernias are in effect hernias through the tendons of the digastric muscles and that the repair of the hernia should take into consideration the lines of musculoaponeurotic pull.

If one carefully examines the linea alba in a large number of cadavers, it will be noted that there is considerable variation in the concentration of the aponeurotic fibers from level to level. It is possible that a congenitally weak area is responsible for the development of an epigastric hernia. However, it can also be observed that there are occasional blood vessels which also pass through the linea alba (Fig. 13), either in the midline or eccentrically placed next to borders of the rectus muscles. It is our opinion that it is the tiny foramina through which these blood vessels pass that provide the opening for the beginning of an epigastric hernia. This opinion is strengthened by the observation that even a very small epigastric hernia (hernia adiposa) is accompanied by one or more small blood vessels which will bleed significantly if the neck of the protruding fat is not ligated.

There is rarely any significant amount of

preperitoneal fat in the posterior aspect of the upper abdominal wall and the peritoneum is closely adherent to the transversalis fascia. However, even in a slender individual, there is always some adipose tissue between the folds of the falciform ligament of the liver. It is this fat that is the presenting part of an epigastric hernia and, in the small hernia adiposa, that represents the entire hernial mass. It is this characteristic of the epigastric hernia which justifies the lipoma theory of Cloquet as the explanation of the cause of this hernia. It is certain that all epigastric hernias begin by the protrusion of a small lobule of fat which, in most instances at least, pushes through a perforating blood vessel foramen. As more fat is pushed out through the defect, the attached peritoneum is eventually pulled through and then a hernia with a peritoneal sac exists. As the hernia enlarges further, omentum and the hollow viscera enter the sac. Most of these hernias are repaired when quite small because they are painful and the patient seeks help early in their development. However, they can attain large size with marked displacement of the corresponding rectus muscle. We have recently repaired such a hernia which measured 10 cm. in diameter at the level of the aponeurotic defect. The hernial sac contained the transverse colon, omentum, gallbladder and several loops of small intestine.

Most epigastric hernias occur either roughly half the distance between the xiphoid process and the umbilicus (Fig. 16 a) or immediately above the umbilicus. It is important to inspect the linea alba just above the umbilicus when repairing an umbilical hernia because, occasionally, one will find an incipient epigastric hernia in this location. It is also important in repairing these hernias to examine carefully the linea alba within the limits of the incision because

Figure 16. Epigastric hernioplasty. a, Appearance of an epigastric hernia. b, Repair of the aponeurotic defect by simple transverse linear closure. c, Sagittal section showing repair of the several layers.

closure is under less tension and should have a lower incidence of recurrent herniation. The umbilical skin is then inverted and the apex of the cone is sutured to the linea alba (Fig. 15 b). The subcutaneous fascia is next closed so that dead space is obliterated around the new umbilicus (Fig 15 c). In applying the dressing, a stent of fine-mesh gauze or silver foil is packed into the umbilical funnel so that a normal-appearing umbilicus is present after the wound has healed. It is important in children to preserve the umbilicus for, in general, children are quick to observe anatomic aberrations and they just as quickly ask questions or make derogatory comments.

The only suitable treatment for an adult umbilical hernia is surgical repair. Although an occasional patient can wear a truss with a soft cushion if the hernia is reducible, in general a truss should not be worn, first, because it will not stay in place and, second, because the pressure is painful and dangerous. The small variety of adult umbilical hernia is repaired in exactly the same manner as the infantile umbilical hernia (Fig. 15 b). The large umbilical hernia presents some technical problems because, to gain mobility of the rigid aponeurotic flaps, it is necessary to cut into the anterior and posterior rectus sheaths on either side. The Mayo overlapping (vest-over-pants) closure (Fig. 15 c) is better than simple linear closure for the large umbilical hernia. An umbilical dimple should also be reconstructed in the adult.

EPIGASTRIC HERNIA

Definition. Strictly speaking, any hernia which occurs in the topographic designation of the epigastrium would be an epigastric hernia. However, for practical purposes, this is a hernia of the linea alba anywhere between the xiphoid process and the umbilicus. Except for incisional hernias in the epigastrium, hernias other than those in the linea alba are an extreme rarity.

Etiology. As in most other hernias, the cause of this hernia is a combination of a congenital aponeurotic defect and an acquired element associated with increased intra-abdominal pressure and muscular effort. Although complete proof is lacking, it is believed that these hernias have their origin in the apertures of perforating blood vessels and that, in this type of hernia, the increased intra-abdominal pressure is due to muscular effort rather than to sources of increased pressure within the abdominal cavity.

Incidence. This is one of the least common of the parietal abdominal hernias, accounting for only 1.6 per cent in an average series of hernioplasties (Table 1). It is found almost entirely in the middle-aged male who is doing manual labor.

Anatomy. These hernias occur almost entirely in the linea alba between the xiphoid process and the umbilicus. Rarely, a hernia is seen in the linea alba just below the umbilicus and, while this hernia occurs in the linea alba, it can hardly be designated an epigastric hernia because of its topographic location. By common usage, however, a hernia in the linea alba just above the umbilicus is called an epigastric hernia even though it lies within the topographic limits of the umbilical region. Hernias through the rectus sheath, or the linea semilunaris in the epigastrium, are so rare that they do not warrant discussion.

Surgeons frequently fall into the error of referring to the rectus sheaths as fasciae. While it is true that the laminae of the rectus sheaths are invested by fascial layers, the fasciae are very thin and densely adherent to the main structure of the sheaths which is, of course, the aponeurotic or tendon fibers of the anterolateral abdominal musculature. The fasciae by themselves have very little intrinsic strength and from a practical surgical standpoint serve only to bind the aponeurotic fibers more closely together. If one dissects the innominate fascia off the external oblique muscle toward the midline, it becomes difficult grossly to differentiate the fascia from the epitendineum. This is similarly true with the transversalis fascia on the posterior surface of the abdominal wall. So with the clear understanding that the rectus sheaths are aponeurotic plates, the next step is to realize that the linea alba is also an aponeurotic structure and not just a fusion of "fascial" layers. It represents the mutual insertion of six flat muscles and, quite understandably, it is a very heavy aponeurotic plate. It is much thicker than either rectus sheath and mathematically should be four times as thick and strong as one layer of the rectus sheath. Because of

muscles, there is considerable criss-crossing and actual interdigitation of aponeurotic fibers within the laminae of the rectus sheaths. While there is considerable variation from level to level and between the anterior and the posterior rectus sheath in the degree of this in " " it is this

aponeurotic fibers of the posterior rectus sheath change over into the anterior rectus sheath. Weakness in this angle, as evidenced by separation of the aponeurotic fibers, was repeatedly observed and especially in those cadavers in which the change-over occurred at several levels so as to give, in effect, two, and sometimes three, margins that could be termed *linea semicircularis*. A protrusion of preperitoneal fat between the aponeurotic fibers of the transversus abdominis (*hernia adiposa*) due to an aponeurotic defect is the etiologic basis of this hernia whatever the contributing causes may be, such as increased intra-abdominal pressure and degenerative changes. Perforating blood vessels in this angle have not been observed, although a small vein which runs parallel to the lateral border of the rectus abdominis muscle is a constant finding at this level. Small protrusions of preperitoneal fat through the transversus abdominis aponeurosis are occasionally seen above the area of a direct inguinal hernia and so this region should be carefully inspected whenever a direct inguinal hernia is being repaired. Their simple reduction and closure of the aponeurotic defects with fine silk sutures seem to be sufficient. Should the hernial defect occur below the point at which the inferior epigastric vessels cross the *linea semilunaris*, it must be termed a diverticular direct inguinal hernia. The variation in the position of the *linea semicircularis* allows considerable variation in the vertical location of this hernia.

From the few Spiegel's hernias we have observed, the presenting mass is preperitoneal fat and it remains for a long time as a vague and slightly tender lump in the interstitial position beneath the external oblique aponeurosis. Fully developed hernial sacs with incarcerated contents have, of course, been reported, but in our four subjects the hernial mass consisted of preperitoneal fat and a small empty hernial sac. The repair of this hernia, after the fat and the peritoneal sac are disposed of in a conventional manner, is of the greatest simplicity. The transversus abdominis aponeurotic fibers, along with the overlying and interdigitating internal oblique aponeurotic fibers, are closed transversely. The overlying external oblique aponeurosis is closed in the oblique direction of its fibers.

LUMBAR HERNIAS

Two types of lumbar hernias have been described—one through the inferior lumbar

triangle of Petit and the other through the superior lumbar triangle of Grynfelt.

The inferior lumbar triangle of Petit is bounded by the superior margin of the posterior crest of the ilium, the anterior border of the latissimus dorsi muscle and the posterior border of the external oblique muscle. The roof of the triangle is the continuity of the muscle fascia and the superimposed subcutaneous fascia. The floor of the triangle consists of the internal oblique muscle fibers, originating from the iliac crest, and beneath, the similar fibers of origin of the transversus abdominis muscle. An inferior lumbar triangle of variable size is present in three-fourths of dissected cadavers. Therefore, the presence of this triangle does not constitute a predilection for the development of a lumbar hernia, although an inferior lumbar hernia must of necessity present through this triangle. Fundamentally, this hernia must be caused by a defect in the transversus abdominis layer first, with subsequent changes taking place in the overlying musculofascial layers. We have noted the absence of segments of the transversus abdominis muscle immediately above the iliac crest, but with the continuity of the layer maintained by the transversalis fascia and supported strongly by the overlying internal oblique muscle layer. While segmental congenital absence of layers undoubtedly accounts for an inferior lumbar hernia present at birth, and a deficient muscular floor in the triangle could explain the appearance of the hernia in an adult, a constant vascular lacuna at the site of the development of this hernia might also explain its origin. The rarity of the hernia, however, attests to the competency of this foramen.

The iliohypogastric nerve and the fourth lumbar artery and vein perforate the transversus abdominis muscle just above the iliac crest and lateral to the quadratus lumborum muscle (Fig. 17) at the point where inferior lumbar hernias occur. It is possible that this hernia begins with the protrusion of retroperitoneal fat into the neurovascular foramen in the same manner of origin as that for some of the epigastric hernias.

The superior lumbar triangle of Grynfelt is bounded by the inferior border of the twelfth rib, the lateral border of the sacrospinalis muscle and the posterior border of the internal oblique muscle. The roof of the triangle is the latissimus dorsi muscle and the floor, the transversus abdominis muscle. As in the inferior lumbar triangle, the dimensions of this triangle vary considerably, but

small defects with hernia adiposa are frequently found adjacent to the main hernial defect. This is especially true in patients in the older age groups in whom fatty infiltration or replacement affects the linea alba as it does many other parts of the body.

Diagnosis. The diagnosis of a fully developed epigastric hernia is easy, but these hernias give symptoms early in their development and can be very difficult to feel, especially in the obese patient. At the stage when the hernia is only a 3- or 4-mm. hernia adiposa, it may give sharply localized tenderness and pain and a referred pain that can mimic that due to duodenal ulcer or gallbladder disease. The sharp localization of tenderness in the contracted abdominal wall helps to differentiate this condition from more deeply placed visceral disease. When the hernia enlarges to the point that there is a peritoneal sac containing viscera, then other symptoms appear associated with omental traction or partial intestinal obstruction just as in any other parietal hernia. The outstanding characteristic of this hernia is the symptomatology which is out of all proportion to its size. The tiny aperture of the early hernia is even more tightly squeezed by muscular contraction, which in turn makes the decussating aponeurotic fibers about the aperture more taut. Parietal somatic nerves and the sympathetic fibers accompanying the blood vessels are tightly compressed and explain the local and referred pain.

Treatment. The only treatment for the epigastric hernia is surgical. The pressure of any type of truss is intolerable because most of these hernias are irreducible and tender. A transverse incision is made over the hernial mass and the subcutaneous fascia is dissected off the hernia and the surrounding linea alba. The hernia is usually tightly incarcerated so that the linea alba must be incised on one or both sides to accomplish reduction. A small lobule of fat may be simply pushed in, but larger lobules should be inspected for a peritoneal sac. If a sac is present, it should be opened to rule out the possibility of incarcerated omentum or viscera. Pedunculated processes of fat should be ligated at their base before excision because of the blood vessels. As a rule, a defect that is no broader than the linea alba can be repaired by simple linear closure in the transverse plane (Fig. 16 b). The method of closure or the type of suture material is of less importance than tight closure in preventing fat lobules from pushing out

between the sutures in the postoperative period, because this will inevitably manifest itself by recurrent epigastric herniation. Epigastric hernias, with an aponeurotic defect larger than the width of the linea alba, which extend into one or both rectus sheaths, present technical problems in repair. The surgical principle that the subcutaneous fascia should be carefully closed to avoid leaving a dead space applies to any incision and is simply illustrated in Figure 16 c.

Two features in the repair of this hernia are worthy of emphasis. First is the careful search for adjacent incipient epigastric hernias which may be separately repaired or included in the main closure when possible. The sutures should be carefully placed so that a suture hole does not become the site of a recurrent epigastric hernia. The second important feature is closure of the defect in the transverse plane. Without belaboring the point, enough has been said to present the realization that the direction of musculo-aponeurotic pull in the linea alba is transverse and that a closure in the vertical plane is subject to powerful disruptive forces.

SEMILUNAR (SPIEGEL'S) HERNIA

The extreme variation in the position and formation of the linea semicircularis, along with variation in the structural strength of the transversus abdominis aponeurosis, is the key to the development of this rare type of hernia. Variations in the internal oblique and external oblique layers, while common, are of lesser importance. In reviewing statistical data obtained from observations upon the structure of the anterior abdominal wall in 250 cadavers, it is amazing that clinical evidence of herniation through or near the linea semilunaris in the lower abdomen is not common. It is possible, since most cadavers are the bodies of aged persons, that these defects in aponeurotic structure represent a degenerative process. It is also likely that protrusions of preperitoneal fat through the aponeurotic fibers of the transversus abdominis layer are very slow in their development into discrete hernias.

Although hernias in the linea semilunaris above the level of the linea semicircularis have been described, aponeurotic deficiency at this level has not been observed, on the contrary, this line of aponeurotic fusion is extremely dense and strong. They must represent hernias through blood vessel foramina (Fig. 13). The angle where the linea semicircularis joins the linea semilunaris is the point at which the transversus abdominis

Every surgeon has had the disquieting experience of seeing a hernia develop in some of his surgical wounds and even though it is due to circumstances beyond his control, it is a tragedy for the patient. The surgeon with a thorough knowledge of the anatomy of the abdominal wall, who understands the importance of the transversus abdominis layer and makes his incisions accordingly and practices sound principles of surgical technique, will only occasionally be confronted with this difficult problem.

We favor the transverse abdominal incision, which preserves the greatest number of musculoaponeurotic fibers, since this incision carries the lowest incidence of incisional herniation. In certain patients the additional exposure afforded by a long vertical rectus incision makes the increased chances of the development of an incisional hernia a justified risk. In the hands of a competent surgeon and in a slender patient with healthy tissues, the vertical wound heals well with a low incidence of herniation. However, the surgeon today is faced with the problem of many seriously ill patients with various degrees of malnutrition whose wounds heal poorly under optimum conditions. In this group, and in the obese with their added problems of wound tension and incidence of infection, the transverse incision that carefully preserves the integrity of the transversus abdominis layer carries a much lower incidence of wound hernia.

Every surgeon should be familiar with the direction of the fibers of the external oblique, internal oblique and transversus abdominis muscles. The anterior and posterior rectus sheaths represent an intermingling and interdigitation of the aponeurotic fibers of insertion of these three muscles as they approach a mutual insertion in the linea alba. The interdigitation of these aponeurotic fibers within the rectus sheaths becomes so complex at times as to suggest the warp and woof of a carpet. The weave is further strengthened by the epitendineae and the fascial laminae, so that at a casual glance the rectus sheath appears to be a dense, tightly woven structure which can be cut in any direction with impunity. However, incisions in the rectus sheath should take into consideration the lines of force or musculoaponeurotic pull.

Above the level of the linea semicircularis the aponeurotic fibers of the transversus abdominis and internal oblique muscles in the posterior rectus sheath have a

predominantly transverse course toward their insertion in the linea alba. As the costal margin is approached, these fibers course in a slightly oblique direction cephalad as they pass from the lateral edge of the sheath to the linea alba. The number of internal oblique aponeurotic fibers gradually decreases until, in the upper epigastrium, the posterior rectus sheath consists entirely of the transversus abdominis musculoaponeurotic fibers. Therefore, in the posterior rectus sheath (Fig. 18 a and b), there can be no question about the direction that a surgical incision should take. A cholecystectomy incision (Fig. 18 b) in the transverse plane can extend from the linea alba to the costal margin by simply separating parallel musculoaponeurotic fibers in the posterior rectus sheath. In a gastrectomy incision these fibers can be separated from one costal margin to the other. If the linea alba and the posterior rectus sheath or sheaths are carefully approximated in the wound closure, the patient has, in effect, a normal posterior layer for the abdominal wall, since no musculoaponeurotic fibers have been cut. As a matter of fact, the contraction of the transversus muscle in the postoperative period only tends to approximate more tightly the aponeurotic fibers which have been separated during the operation.

The musculoaponeurotic dynamics in the anterior rectus sheath are not quite so simple. The external oblique aponeurotic fibers course obliquely downward and the aponeurotic fibers of the internal oblique in the anterior rectus sheath course obliquely upward. As their respective aponeurotic fibers enter into the formation of the anterior rectus sheath, there is an intimate intermingling and interdigitation. Because these aponeurotic fibers are rather firmly united, they act as a unit. The predominant force of their combined pull is still in the transverse plane, although some fibers of the external oblique will tend to pull the superior margin of the incision cephalad and some fibers of the internal oblique will tend to pull the inferior margin of the incision caudad. While a transverse incision in the anterior rectus sheath is not ideal because aponeurotic fibers are cut, it is the best available direction for cutting the anterior rectus sheath.

The ideal abdominal incision is the small muscle- and aponeurosis-splitting right lower quadrant incision used for an appendectomy. The external oblique aponeurosis is divided obliquely in the direction of its fibers and the edges are retracted. At this

LUMBAR HERNIAS

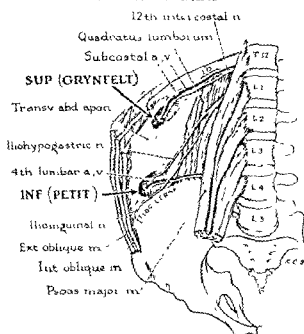

Figure 17 Anterior view of the right posterior abdominal wall to show the points of origin of the superior and inferior lumbar hernias. The peritoneum, retroperitoneal connective tissue and the transversalis fascial layer have been removed. The course of the nerves and vessels illustrated represents one theory of the etiologic basis of these hernias.

the bulwark against herniation is the integrity of the transversus abdominis musculoponeurotic layer. It is interesting to observe that the subcostal artery and vein and the twelfth intercostal nerve perforate the transversus layer in the floor of this triangle (Fig. 17) at the point of origin described for superior lumbar hernia. Again, it is suggestive evidence that a neurovascular lacuna is the origin of this hernia. Whatever technique of hernia repair is used, reconstruction of the transversus abdominis layer should be the primary objective.

INCISIONAL HERNIA

Definition. An incisional hernia is one which develops in the scar of a surgical incision.

Etiology. Irrespective of the many contributing causes to the development of an incisional hernia, it is fundamentally a failure of the approximated musculoponeurotic and fascial layers to remain in apposition.

Wound infection is probably still the most important factor in the development of an incisional hernia. Suppurative necrosis destroys the approximated margins of the aponeuroticofascial layers irrespective of the type of suture material used, and if catgut suture has been used, it undergoes dissolu-

tion and fragmentation at a very rapid rate.

Drains through the abdominal wall greatly increase the incidence of incisional hernia, as evidenced by the number of these hernias that develop at drain sites. This is due to incomplete closure of the wound plus the added element of infection. Other causes of incisional hernia may be grouped under several headings.

Faulty wound technique includes a host of errors of both omission and commission. The most important include inadequate hemostasis, avascular necrosis of the layers due to sutures too tightly tied, faulty closure of the posterior rectus sheath or transversus abdominis layer, rough handling of tissue and wound contamination from several sources.

The **preoperative status** of the patient, which includes obesity, malnutrition, hypoproteinemia, vitamin deficiency (especially vitamin C) and tissue edema, may be a factor.

The **postoperative status** of the patient which includes abdominal distention, chronic cough and inadequate nutrition, may play an important role.

The **type of incision** also has some bearing upon the incidence of incisional herniation. All other factors being equal, there is not only a higher incidence of herniation through vertical incisions than there is through transverse muscle-splitting incisions but hernias through vertical surgical scars are more difficult to repair than those through transverse scars.

Incidence. It is impossible to ascertain the true incidence of incisional herniation because no long-term follow-up studies are available on a large series of cases. However the percentage of incisional hernioplasties in recent series of consecutive hernioplasties would indicate that the incidence of the hernia is increasing (Table 1). This percentage, of course, is no index of the incidence of incisional hernia after celiotomy. It is also true that the number of operations performed is increasing year by year. Whatever the true incidence of incisional hernia may be as related to the total number of celiotomies, it is distressingly high when one considers the almost insurmountable difficulties encountered in the repair of many of them. The surgeon should thoughtfully consider the fate of his surgical incision as he dramatically cures the patient of some intra-abdominal disease.

Anatomy. The pathologic anatomy of the incisional hernia is a story of surgical failure.

the integrity of the more superficial musculoaponeurotic layers. On the other hand, if the transversus abdominis layer remains intact, a hernia will not develop even though the more superficial musculoaponeurotic layers are imperfectly approximated or subsequently become separated in the postoperative period. The rectus abdominis muscle can be sectioned within its sheath with impunity. If the epigastric blood vessels which course within the muscle substance are ligated to avoid a hematoma, the severed rectus abdominis muscle heals as an auxiliary tendinous inscription.

The vertical rectus incision is by far the most common celiotomy incision in use today. It is an incision that is easily and rapidly made with a minimum of time spent in ligating blood vessels. The exposure is excellent when the incision is long enough and it is rapidly closed with a continuous catgut suture. When speed and wide exposure are needed, it is the incision of choice. However, as an example of wide exposure using the transverse incisions, it can be pointed out that a total colectomy and proctosigmoidectomy can be very nicely accomplished through a combination of upper and lower abdominal transverse incisions. This combined approach adds very little to the total operating time, gives excellent exposure from pelvis to subdiaphragmatic spaces and leaves the patient with a strong abdominal wall. A commonly cited advantage of the vertical incision is that it can easily be extended, either up or down, in the event that the pathologic process is not accessible through the original incision. One of the more common incisional hernias is in the vertical cholecystectomy incision which was converted into an appendectomy incision by caudal extension or in the appendectomy incision extended upward to include a cholecystectomy incision. This long tendon-severing incision, plus the high incidence of suppuration in the gallbladder and in the appendix, accounts for the excessive number of incisional hernias which occur in the right rectus incision. The advocates of "exploratory laparotomy" naturally favor the vertical incision because of the ease with which it can be extended. After careful study of the patient, a definite diagnosis should be made along with an appropriate transverse incision. Should the diagnosis and the surgical approach prove to be in error, another transverse incision should be made at the proper site.

The vertical rectus incision cuts all of the

aponeurotic fibers in the rectus sheaths for the length of the incision. As soon as the patient recovers from the anesthetic, the contraction of the muscle fibers whose aponeurotic fibers have been cut puts tremendous tension upon the line of wound closure. By letting the patient come out of the anesthetic until he can close the glottis and strain, we have found the power of the muscle pull to be as high as 40 pounds in a well-developed male. When a transverse incision is used the divided fibers of the transversus abdominis snap together and can be sutured without any tension. This, of course, does not apply to the anterior sheath which is composed of internal oblique and external oblique fibers and a pull of up to 12 pounds has been necessary to approximate the anterior sheath with the glottis closed. However, it is the transversus abdominis layer which is of the greatest importance in the prevention of wound hernia.

Figure 18 was prepared to emphasize some of the foregoing points. An incisional hernia in a vertical cholecystectomy incision (Fig. 18 a) is presented for comparison with an incisional hernia in a transverse cholecystectomy incision (Fig. 18 b). While the two hernias are not comparable in size, they do represent our average findings in repairing incisional hernias in cholecystectomy scars. We have no way of estimating the incidence of incisional hernia in the vertical cholecystectomy incision since we have never used this incision. However, in over 400 cholecystectomies in which the transverse incision was used, we have had two incisional hernias develop in the lateral pole of the wound at the former drain site with a defect as shown in Figure 18 b. During the same length of time, we have repaired thirty-four incisional hernias in vertical cholecystectomy scars and observed an unrecorded large number of badly attenuated scars that are thin and bulging but without a discrete aperture that can be designated as a hernia. By comparing these two figures, the myodynamics in the development of each hernia should be readily apparent. Whatever the original cause for the failure of the wound edges to stay in apposition (Fig. 18 a), the most important contributing cause is the muscular pull which can only be shown for the transversus abdominis musculoaponeurotic apparatus in this posterior view. The heavy arrows indicate the direction of muscular pull which is at right angles to the incision and is therefore maximal. One must take into consideration the

Figure 15. Incisional hernias a, Posterior view of the anterior abdominal wall showing the aponeurotic defect of a large incisional hernia in a vertical right rectus cholecystectomy incision b, Posterior view of the anterior abdominal wall showing the usual musculoaponeurotic defect of a transverse cholecystectomy incision c and d, The thread and rubber band analogy between the transversus abdominis muscle and the aponeurotic fibers of the transversus abdominis muscle

level, the transversus abdominis and internal oblique musculoaponeurotic layers have an identical course and so these fibers are separated parallel with their course, which is in the transverse plane. This incision, properly made, does not cut a single musculoaponeurotic fiber. If the transversus abdominis and its fascia, the transversalis fascia, are carefully closed so that preperitoneal fat cannot push out between the fibers, this wound is as strong after the operation as a normal abdominal wall. The incision should never result in incisional herniation unless it has been necessary to leave a drain through the

abdominal wall. The larger transverse abdominal incision is a compromise to adequate exposure. More accurately, it is a compromise only in regard to the anterior rectus sheath, for the posterior rectus sheath and the transversus abdominis muscle fibers can be separated from one side of the body to the other without cutting tendon fibers. It is worth re-emphasizing at this point that the transversus abdominis musculoaponeurotic layer is the most important bulwark against the development of an incisional hernia. If a defect develops in the transversus layer a hernia is born, irrespective of

Diagnosis. The diagnosis of a fully developed incisional hernia presents no difficulties because it is obvious to the patient and the physician alike. However, small or incipient incisional hernias may be difficult to feel in the surrounding scar and this is especially true in the obese patient. Until a defect can be felt with the examining finger along with an impulse on coughing, one cannot definitely diagnose an incisional hernia. Many surgical scars are tender for a long time after the operation with episodes of sharply localized pain and tenderness following strenuous muscular effort. These latter episodes probably represent tearing of scar tissue with small areas of hemorrhage and the acute symptoms will subside in a week or two. Broad and attenuated vertical abdominal scars are a common finding, but they do not constitute a true hernia unless there is a circumscribed defect through the scar. The surgeon should not contemplate repairing thinned-out scars unless it becomes necessary to operate upon the patient for adhesive intestinal obstruction, because there is no assurance that a better end result can be obtained.

It is difficult to describe the symptoms of an incisional hernia. An objectively severe incisional hernia may cause only the vaguest of symptoms, while an apparently insignificant defect may be very painful and be associated with the whole gamut of symptoms which accompany partial or complete intestinal obstruction. In general, the symptoms of an incisional hernia are mild, considering the rigidity of the defect and size of the hernial protrusion. These hernias are more often incarcerated than reducible and only a small percentage of them become strangulated. They gradually increase in size and become more difficult to repair with the passage of time; therefore nothing but increasing difficulty is to be gained by procrastination.

Incisional hernias frequently present multiple defects with septa separating the apertures. These septa represent portions of the wound closure that have held together. In addition to the aponeurotic defects, which represent separate hernial rings, the omentum that is invariably present and incarcerated within the hernial sac will make additional secondary hernial rings which account for the fact that these hernias are so frequently irreducible. It is also common to find a portion of the hernia regularly reducible while other segments cannot be reduced into the abdominal cavity. Frequent

findings at the time of operation are unsuspected interstitial components of the hernia which have dissected between the rectus sheaths. Incisional hernias may attain enormous size and contain all of the viscera with a mesentery plus some of the so-called fixed viscera as components of a sliding hernia. While these patients are usually confined to a sedentary life, they are usually free of symptoms of intestinal obstruction.

The hernial sac of an incisional hernia which is fully developed lies immediately beneath the skin so that peristaltic movement can be plainly seen. At times the skin is so tightly stretched that it appears about to break. Trophic changes in the skin over a large incisional hernia are common along with ulcers that are due to simple avascular necrosis.

Treatment. The repair of an incisional hernia is a complex problem. This hernia is a perfect example of the old aphorism that an ounce of prevention is worth a pound of cure. Once a large incisional hernia has developed in a vertical rectus incision, all methods of surgical repair are at best only makeshift and the incidence of recurrent herniation is appalling. The most important single feature in the prevention of an incisional hernia is the careful preservation of the integrity of the transversus abdominis muscle and its aponeurosis. This is accomplished by separating the musculoaponeurotic fibers in the transverse plane and not by cutting them in the vertical plane.

Trusses of the usual spring variety, with a ball or cushion that presses against the hernial defect, cannot be used in incisional hernias which are incarcerated and cannot even be kept in place for the occasional reducible incisional hernia with a single discrete defect. An elastic support, such as a two-way stretch girdle, will afford considerable relief in some instances while in others even very slight pressure increases the discomfort. For very large incisional hernias, a cloth and elastic support which is in effect a sling or hammock can be worn with some amelioration of symptoms because it supports the weight of the hernia and reduces the traction upon the mesentery of the contained viscera.

In general, a small incisional hernia should be repaired by developing the layers of the three anterolateral abdominal musculoaponeurotic laminae and approximating each in the direction of its fibers, with special attention to the reconstruction of a firm transversus abdominis layer. When this is

Diagnosis. The diagnosis of a fully developed incisional hernia presents no difficulties because it is obvious to the patient and the physician alike. However, small or supple incisional hernias may be difficult to feel in the surrounding scar and this is especially true in the obese patient. Until a defect can be felt with the examining finger along with an impulse on coughing, one cannot definitely diagnose an incisional hernia. Many surgical scars are tender for a long time after the operation with episodes of sharply localized pain and tenderness following strenuous muscular effort. These latter episodes probably represent tearing of scar tissue with small areas of hemorrhage and the acute symptoms will subside in a week or two. Broad and attenuated vertical abdominal scars are a common finding, but they do not constitute a true hernia unless there is a circumscribed defect through the scar. The surgeon should not contemplate repairing thinned-out scars unless it becomes necessary to operate upon the patient for adhesive intestinal obstruction, because here is no assurance that a better end result can be obtained.

This is accomplished by separating the musculoaponeurotic fibers in the transverse plane and not by cutting them in the vertical plane.

Trusses of the usual spring variety, with a ball or cushion that presses against the hernial defect, cannot be used in incisional hernias which are incarcerated and cannot even be kept in place for the occasional reducible incisional hernia with a single discrete defect. An elastic support, such as a two-way stretch girdle, will afford considerable relief in some instances while in others even very slight pressure increases the discomfort. For very large incisional hernias, a cloth and elastic support which is in effect a sling or hammock can be worn with some amelioration of symptoms because it supports the weight of the hernia and reduces the traction upon the mesentery of the contained viscera.

In general, a small incisional hernia should be repaired by developing the layers of the three anterolateral abdominal musculoaponeurotic laminae and approximating each in the direction of its fibers, with special attention to the reconstruction of a firm transversus abdominis layer. When this is

impossible, the fused layers should be approximated in the transverse plane with an overlapping closure similar to the Mayo operation for large umbilical hernias. When tension precludes such a vest-over-pants closure, simple linear closure with less tension is the better procedure.

Unfortunately, long vertical oval defects are commonly seen and for these there is no good solution. They cannot be approximated in the transverse plane and to reapproximate the edges forcibly in the vertical plane carries a very high incidence of recurrent herniation. It is for this reason that various prosthetic devices have been tried to strengthen the line of closure or to fill in the gap when the edges cannot be approximated. Without going into detail, some of the devices that have been used are broad homologous sutures of fascia lata, aponeuroticofascial flaps either turned with their blood supply preserved or transplanted from another part of the body, patches of ox fascia, patches of plastic cloth, full-thickness or split-thickness patches of skin and sheets of metallic wire mesh. None of them is a complete answer to the problem and all of them, with the exception of the musculo-aponeurotic flap with its blood supply intact, eventually result in a layer of scar tissue as the sole bulwark against recurrent herniation. Scar tissue slowly stretches and the broader the amount of scar tissue in a wound, the greater will be the eventual attenuation of the hernial repair. While it is ideal to turn a musculoaponeurotic flap with its blood supply intact in the repair of a midabdominal defect, the technical problems are insurmountable.

Through the years, we have tried most of the described prosthetic devices, but recently we have relied entirely upon the wire mesh advocated by Koontz as being the simplest and most effective. At first we used the tantalum mesh, but lately we have used stainless steel wire mesh because it is less brittle and more easily handled in the wound. Stainless steel suture material is much easier to use than tantalum and, although the galvanic action of different metals in the same wound might not be important, we have never tried the use of more than one in a wound.

The fate of the wire mesh and the eventual strength of the wound have been interesting to observe. All metal has a fatigue point at which it breaks and the movement of the abdominal wall in breathing and bending eventually fragments the

wire mesh rather completely (Figs. 19 and 20). Although the wire mesh acts as a firm support in the first few months after the operation, the eventual support is only scar tissue. What happens after the wire mesh fragments is largely dependent upon the habitus and habits of the patient. As an example, the case histories of two patients will be compared.

The first patient (Fig. 19) had a cholecystectomy and appendectomy in 1935 through a long vertical rectus incision. Within a few months after the operation, he noticed a lump in the incision which gradually enlarged through the years. When first seen by us in 1951 he had a strangulated incisional hernia the size of a football with an aponeurotic defect that measured 10 cm. in diameter. He was obese (225 pounds) and the edges of the defect were approximated with considerable tension. A sheet of stainless steel wire mesh was sutured in place over the suture line. Following this operation, he seemed to have a very strong abdominal wall, but against our advice he remained obese, physically active and would not wear an elastic girdle. He was not seen from 1952 until 1955 when he returned with an incisional hernia through the fragmented

Figure 19. A sketch of an x-ray plate to show a recurrent incisional hernia through the fractured fragments of wire mesh.

wire mesh (Fig. 19) that was irreducible and with partial intestinal obstruction. It should be noted that the scar which incorporated the fragments of the wire mesh was exceedingly tough and yet a hernia had occurred through this scar. The patient was still obese and now had moderately severe myocardial damage. The margins of the hernia were defined after a difficult dissection, the hernia reduced and the dense margins, including fragments of wire mesh, were simply approximated with wire sutures in the transverse plane.

Figure 20 A sketch of an x-ray plate to show the fractures in a large sheet of wire mesh that was used to repair the defect in a very large incisional hernia.

The second patient (Fig. 20) had a cholecystectomy and appendectomy in 1923 through an incision that extended vertically from the right costal margin to within 4 cm. of the pubic tubercle. When first seen in 1951, he had an enormous incisional hernia with recurrent episodes of intestinal obstruction. This patient was slender (126 pounds), but, even so, the edges of the defect could not be approximated. The fused flaps of the hernial sac were used to bridge the defect and supported with a large sheet of wire mesh. This patient has remained thin, worn an elastic two-way stretch girdle most of the time and has done no heavy work of any kind. He has continued his trade of repairing shoes. He was called in for an examination in May, 1955, at which time the x-ray picture was taken from which the drawing shown in Figure 20 was made. Clinically, the repair is solid although the wall is thin and some of the fractures in the wire mesh can be felt.

These two cases reports emphasize the fact that the cooperative slender patient can be given reasonable assurance that the repair of his large incisional hernia will be successful. The obese obdurate patient is doomed to failure of the repair and should not be operated upon unless intestinal obstruction makes it necessary. The obese patient with a large incisional hernia, who will not reduce his weight to normal and will engage in heavy physical work, had better kept his hernia, for the second recurrence will undoubtedly be more troublesome than the first.

HERNIAS OF THE RESPIRATORY DIAPHRAGM

Definition. A diaphragmatic hernia represents the protrusion of an abdominal viscus or viscera into the thoracic cavity through an aperture in the respiratory diaphragm.

Etiology. From an etiologic standpoint, the diaphragmatic hernias may be divided into three groups: those due to congenital segmental absence of a portion of the diaphragm; those due to congenital weakness or imperfect fusion of the diaphragmatic segments; those due to traumatic perforations or rents in the diaphragm. The first group represents a defect in the embryologic development of the diaphragm and most commonly the left pleuroperitoneal segment of the diaphragm is involved. These hernias are present at birth and, unless they are very small, produce profound and immediate symptoms. The second group includes those hernias which are due to imperfect fusion of the various embryologic segments of the diaphragm. Esophageal hiatus hernias are also included in this group because most of them are due to an imperfect closure of the esophageal hiatus. Even those hiatus hernias which are due to a congenitally short esophagus have a developmental defect of the hiatus in that this structure fails to close properly because of the thoracoabdominal position of the stomach. Even the adult hiatus hernia

ponent in it. The third group includes all acquired hernias which develop after trauma, whether the trauma is due to direct perforation or to indirect force.

Incidence. It is difficult to determine the true incidence of hernias of the respiratory diaphragm. Wide discrepancies in the reported occurrence of this hernia (Table 1) reflect the source of the statistics. Because of the difficulties involved in the diagnosis and especially in the treatment of diaphragmatic hernias, the large medical centers report an actual as well as a relative increase in these hernias during the past twenty years. The relative incidence of the various diaphragmatic hernias will also depend upon the source of the material. Harrington's statistics from the Mayo Clinic show a great preponderance of esophageal hiatus hernias because his group of subjects is largely composed of adults. Gross' statistics show a preponderance of hernias through the left pleuroperitoneal space, because his group represents the newborn and the infant por-

tion of the population. If one were to attempt to compile statistics from the general population, they would also be in error because of the infants with diaphragmatic hernias who die shortly after birth with a diagnosis of "blue baby" due to a cardiac abnormality and those adults in whom the diagnosis is not established, either because the hernia is asymptomatic or because inadequate diagnostic studies are made. Consecutive hernioplasties will give varying percentages of diaphragmatic hernias which are dependent upon the source of the material. Asymptomatic esophageal hiatus hernias are a common finding in careful routine x-ray examinations of the upper gastrointestinal tract.

Anatomy. All but the traumatic hernias have their inception in a developmental fault. A thorough knowledge of the normal anatomy of the diaphragm is essential for proper surgical repair of these hernias and likewise the origins of the various segments and their musculoaponeurotic composition and mutual insertion in the central tendon are essential information.

Complete absence of the respiratory diaphragm is a very rare autopsy finding in the newborn, but, by careful dissection, fragments of the septum transversum and a cuff of costal attachment can be found. From a practical standpoint, diaphragmatic hernias due to a developmental anomaly are usually concerned with a segmental failure of development in the posterior pleuropertoneal component and are known as pleuropertoneal hernias or hernias through the pleuropertoneal foramen of Bochdalek (Fig. 21). This segment may be absent in part or completely absent. Occasionally the corresponding part of the septum transversum is also deficient so that the hemidiaphragm is totally wanting. Segmental absence of the diaphragm is six times more common on the left side than on the right, presumably owing to the presence of the large right lobe of the liver. When the pleuropertoneal segment is missing, there is free communication between the abdominal cavity and the hemithorax, which means that there is no hernial sac of either peritoneum or pleura. In this type of defect, the hemithorax is completely filled with abdominal viscera and not only is the homolateral lung collapsed, but there is shift of the heart and mediastinal structures to the opposite side with partial compression of the opposite lung. This situation is not compatible with

life and unless corrected very shortly after birth results in death of the infant.

A common finding in cadaver dissections is a small cleft over the lateral lumbo-costal arch in which the pleura is in direct contact with the retroperitoneal fat adjacent to the superior pole of the kidney (Fig. 21). This may be considered the final line of closure of the pleuropertoneal segment. In between this small cleft, which may be considered normal, and complete absence of the pleuropertoneal segment, various quantitative deficiencies exist. The larger ones do not have a pleuropertoneal sac and are symptomatic immediately after birth. The smaller hernias of this type represent failure of the muscle to develop between the layers of the pleura and the peritoneum and they therefore have a combined pleural and peritoneal sac. More commonly, they develop so far posteriorly that the retroperitoneal organs protrude into the thorax with pleura alone forming the hernial sac (Fig. 21). The smaller pleuropertoneal defects prevent immediate herniation and the hernia develops very slowly so that symptoms, or diagnostic evidence of herniation, may not appear until adulthood or they may remain so small that they are an incidental autopsy finding.

Of the lesser apertures through the respiratory diaphragm, only one permits the development of a hernia. This is the cleft between the costal and sternal attachments of the diaphragm through which the superior epigastric vessels regularly pass. These vessels are surrounded by a small amount of fat and areolar tissue that is continuous above with the areolar tissue in the anterior mediastinum and below with the preperitoneal connective tissue. A hernia through this cleft

muscular development about the foramen of Morgagni. When discovered in infancy, it must be due to a developmental defect for it has a peritoneal sac and may contain liver or a loop of a hollow viscus. In the adult, a congenitally large foramen of Morgagni must be the underlying etiologic factor, but the secondary factors of obesity and increased intra-abdominal pressure also play a role, because the presenting mass of the hernia is preperitoneal fat with the peritoneum pulled through secondarily (Fig. 21). This hernia is never very large, but instances have been reported in which it protrudes into the pericardial sac.

The remaining type that is congenital in origin is the esophageal hiatus hernia (Fig. 21). In adult statistics, this appears as the most common of all the diaphragmatic hernias. Hernias through the two other major apertures, the aortic and inferior vena caval hiatuses, have not been recorded. The pathologic anatomy of the esophageal hiatus hernia may be very simply described as a hiatus that is too large, so that a pouch of peritoneum and the adjacent fundus of the stomach are forced through the hiatus by the differential pressures within the abdomen and the thorax. The esophagogastric junction may remain fixed at its normal level below the diaphragm so that the hernia consists of fundus and eventually a portion of the body of the stomach or the esophago-

gastric junction may advance through the hiatus as the leading part of the hernia. When this situation prevails, the hernia must be differentiated from an additional variety of esophageal hiatus hernia that is due to a congenitally short esophagus. Whereas congenital factors exist in both types of hiatus hernias, when there is a congenitally short esophagus the child is born with the upper portion of the stomach in the posterior mediastinum. When the esophagus is of normal length and the hernia develops because of a large hiatus, the hernia appears gradually after birth and the establishment of negative intrathoracic pressure. The rapidity with which an esophageal hiatus hernia develops is directly related to the size of the hiatus. Although the construction of the

HERNIAS OF THE RESPIRATORY DIAPHRAGM

Figure 21. A view of the superior surface of the respiratory diaphragm to show the various types of diaphragmatic hernias.

esophageal hiatus by the crural fibers of the diaphragm is figured correctly in a general way, there is considerable variation in the size of the hiatus as well as the strength of the muscular margins. The hiatus is never a fixed or rigid aperture, as can be demonstrated during any upper abdominal celiotomy by the fact that one or two fingers may be passed into the hiatus along the side of the esophagus. If this were not so, a large bolus of food could not pass through the distal esophagus. It is not possible to state just what the measurements of a normal hiatus should be because of the variation in size of cadavers that do not have an associated hernia. The frequency with which small hiatus hernias are found in the obese adult population suggests that there is an acquired element in the development of some of these hernias which is secondary to obesity and increased intra-abdominal pressure. A roentgenologically demonstrable and symptomatic hiatus hernia in an obese patient or a pregnant woman will frequently become asymptomatic with weight reduction or after delivery.

Most traumatic diaphragmatic hernias involve the tendinous dome of the left hemidiaphragm (Fig. 21), because the right lobe of the liver will seal small perforating wounds and dissipate the indirect force so evenly that the right dome is rarely lacerated. A small perforating wound of the left hemidiaphragm, which permits a tag of omentum to enter the left pleural space, is the beginning of a diaphragmatic hernia that may take a long time to develop into a symptomatic hernia. Large rents in the diaphragm due either to direct or indirect violence result in the immediate development of a hernia. The traumatic diaphragmatic hernia does not have a peritoneal sac, although adhesions may prevent open communication between the abdominal and pleural cavities. Aside from the perforating wounds so common in warfare, crushing injuries are the most common cause of this hernia. The force may be due to abdominal trauma and the diaphragm may be torn by the force of the sudden increase in intra-abdominal pressure. More commonly, the tear is due to force applied directly to the circumference of the lower thorax. The fracture of a rib along the costal origin may tear the adjacent diaphragm or the sudden anteroposterior or lateral compression of the thorax with the diaphragm contracted may tear the central tendon without rib fracture. After a small rent in either hemidiaphragm,

the constant pressure differential after a time may result in bizarre findings at operation. For example, we have seen half of the right lobe of the liver in the right pleural space connected to the infradiaphragmatic portion by a 5-cm. isthmus that represented the diameter of the defect in the diaphragm. On the left, we have observed the spleen as a bilobate organ with the edge of the hernial defect almost bisecting it. Thus some "oozing" of a solid viscus through an aperture much smaller than the organ itself we have also observed in a right pleuropertoneal hernia.

The final type of diaphragmatic hernia is that due to suppurative necrosis from a subdiaphragmatic abscess (Fig. 21). While this mechanism in the production of a diaphragmatic hernia has been described, suppurative necrosis of the diaphragm more commonly results in a fistulous connection with a lower lobe bronchus. This is because the diaphragmatic surface of the lower pulmonary lobe becomes adherent to the infected diaphragm long before an actual perforation exists.

Diagnosis. The incidence of the diagnosis of a diaphragmatic hernia is directly cor-

ception of the large congenital defects in the newborn or the large traumatic defects in the adult with their dramatic symptoms and findings, the symptoms of a diaphragmatic hernia are usually vague. When the herniation is acute the symptoms simulate those due to acute disease of the heart, lung or gastrointestinal tract. The physical findings may be equivocal and, unless the physician suspects a diaphragmatic hernia and orders appropriate x-rays, the patient may be dismissed with some other diagnosis. The routine x-ray examination of the chest has disclosed many an unsuspected diaphragmatic hernia. Small hernias through the parasternal foramen or the pleuropertoneal foramen, especially on the right side, may be totally asymptomatic and be incidentally discovered on a routine chest x-ray film. When this occurs, they must be considered in the differential diagnosis of intrathoracic neoplasms.

The prompt diagnosis of a congenital diaphragmatic hernia in the newborn is of the utmost importance if the child is to survive. In every infant who has respiratory difficulty immediately after birth the possibility of a diaphragmatic hernia should be considered. The "blue baby" with a sea-said abdomen,

chest which is dull or flat to percussion on the left side, associated with the heart shifted to the right, has *prima-facie* evidence of a congenital diaphragmatic hernia through the left hemidiaphragm. Air will not be present in the stomach or intestine immediately after birth to aid in the diagnosis, but a simple anteroposterior x-ray examination will usually clinch the diagnosis. If doubt exists, a small polyethylene tube may be passed into the infant's stomach and a small amount of Lipiodol injected for a contrast study. As there is danger that any ingested or injected material may be aspirated by the newborn, the use of barium is contraindicated because of its irritating effect on the tracheobronchial tree.

Aside from the hernia occurring in the infant in whom the symptoms are resolved into objective findings, the symptomatology of the diaphragmatic hernias is so varied that no group of symptoms may be ascribed to a given diaphragmatic hernia. In general, the symptoms may be divided into those referable to the gastrointestinal tract, the heart and the respiratory system, depending upon the size of the hernia, its location and the pressure it exerts upon its contents.

A loop of intestine constricted by the hernial ring produces signs and symptoms of intestinal obstruction which are no different from those presented by a constricted loop of bowel in an indirect inguinal hernia. However, a host of symptoms frequently accompanies the diaphragmatic hernias that are not present in the common varieties of parietal abdominal hernias because of the frequent involvement of the stomach in the diaphragmatic hernia. Complaints referable to the stomach or of dysphagia are common symptoms with esophageal hiatus hernia. Constriction of the stomach where it passes through the hiatus, angulation of the cardio-esophageal junction and scarring secondary to peptic ulceration all cause mechanical obstruction with resultant dysphagia. A temporary obstruction may follow sudden distention of the thoracic portion of the stomach by swallowed liquid, food or air. This is relieved promptly by vomiting or gradually as the material passes into the stomach below the diaphragm. All of the symptoms of gallbladder disease and diseases of the stomach, duodenum and pancreas can be simulated by an esophageal hiatus hernia. Varices or ulceration of the herniated stomach may cause hematemesis. Carcinoma of the distal esophagus or cardia of the stomach may cause a hiatus hernia or may re-

semble it both subjectively and objectively. Constriction of the distal esophagus by angulation may closely resemble carcinoma.

A diaphragmatic hernia which presses upon or displaces the heart may have many symptoms that appear to be cardiac in origin: tachycardia, substernal pressure or pain and a choking sensation due to extrasystoles. Even a small hernia that cannot possibly interfere with the heart will frequently give cardiac symptoms that must be reflex in origin. The same symptoms are reflexly produced by gaseous distention of the stomach or the splenic flexure of the colon. While these cardiac symptoms are usually of major concern to the patient, they are of no organic importance unless the heart is grossly displaced, as occurs in association with the congenital hernia of the newborn or large traumatic rents in the diaphragm. Even so, the respiratory embarrassment is far more important, for the heart can work effectively in a variety of positions.

Diaphragmatic hernias which cause compression atelectasis of the ipsilateral lung will, at their outset, cause respiratory embarrassment in direct proportion to the amount of lung collapsed and the degree of mediastinal shift to the opposite side. A diaphragmatic hernia, due to trauma, that has been present for some months and has enlarged gradually may displace a considerable portion of the corresponding lung and yet the patient does not complain of shortness of breath. A compensatory mechanism has been established similar to that occurring in the pneumothorax patient whose respiratory complaints are minimal except with exertion. The mediastinum becomes fixed and does not move with changes in pressure. This same patient may have episodes of discomfort and dyspnea when the contained stomach or bowel is distended with air. The symptoms promptly disappear with belching or expelling flatus, but this sequence of events is also characteristic of many other intra-abdominal conditions.

Esophageal hiatus hernias frequently cause only the mildest of symptoms which are passed off by the patient as "acid indigestion," dyspepsia, heartburn, ulcers or gallbladder trouble. Because of the mildness of the symptoms, their intermittency and the prompt response to any of the antacids, the patient does not usually come to the doctor until the symptoms become more persistent and respond less readily to home remedies. The careful roentgenologic examination of this group of patients will reveal a high in-

cidence of esophageal hiatus hernias. These hernias, as well as the adult types of pleuroperitoneal and parasternal hernias, are frequently asymptomatic and are accidentally discovered during a routine x-ray examination of the chest or during upper gastrointestinal study. A presumptive diagnosis of a left-sided diaphragmatic hernia may be made by auscultation if bowel sounds are heard high in the left side of the chest and breath sounds are absent. However, a condition known as eventration of the diaphragm will give the same physical findings. In this latter condition, the diaphragm is greatly stretched and attenuated, contains very few muscle fibers and the dome lies high in the hemithorax. Motion is slight and paradoxical. The condition is symptomless, is not a hernia and does not require any type of treatment. Eventration is probably congenital in origin, although a similar picture is presented by a patient who has had the phrenic nerve interrupted years before. A very striking elevation of an atonic hemidiaphragm is seen in those patients who have artificial pneumoperitoneum in combination with phrenic nerve interruption for the treatment of pulmonary tuberculosis. It should be apparent that the final diagnosis is dependent upon x-ray examination, usually with the aid of a contrast medium in the intestinal tract. A right pleuroperitoneal hernia with a globular protrusion of the liver into the right costovertebral angle may be impossible to differentiate from an extrapulmonary tumor, such as a neurofibroma, in this location.

Treatment. The asymptomatic esophageal hiatus hernia does not require treatment. A hernia adiposa of the parasternal foramen of Morgagni and a herniation of the liver through a right-sided pleuroperitoneal foramen of Bochdalek do not need treatment when asymptomatic if one can be sure of the diagnosis. However, they so closely resemble extrapulmonary but intrathoracic solid neoplasms that an operation is usually indicated. It is well to remember that paralysis of the corresponding hemidiaphragm by interruption of the phrenic nerve in the neck is occasionally indicated in the elderly poor-risk patient and it may give palliative relief of symptoms. It may also greatly embarrass respiration in the patient with emphysema and minimal respiratory reserve. The obese patient with a symptomatic esophageal hiatus hernia may become completely asymptomatic with the proper weight reduction. Some subjects become asymptomatic by ob-

serving a few simple precautions such as remaining upright after a meal, avoiding overeating and the drinking of carbonated beverages, eating slowly, reducing their weight and avoiding heavy lifting. When these remedies fail, then surgical correction of the hernia is indicated.

The congenital diaphragmatic hernias in the newborn require immediate surgical correction. Nothing but increasing difficulties and disaster attends procrastination in infants with congenital, segmental absence of the diaphragm. Properly managed, the newborn withstands an operation very well and the technical problem of restoring the viscera to the abdominal cavity is simplified if operation is performed before the intestinal tract contains food and air. Because the affected hemithorax communicates freely with the abdominal cavity, positive pressure anesthesia must be instituted before the abdominal cavity is opened. The anesthetic mixture must be high in oxygen content and for this reason cyclopropane is the anesthetic of choice. However, for a variety of reasons, we have always used ether. A special infant anesthetic machine must be used because these patients cannot circulate the gases in an adult type of closed system as a result of their small respiratory excursion. A cut-down is established before the operation is started for the administration of water and electrolytes as well as for replacement of blood loss. Blood loss is carefully estimated during the operation because the infant's circulating blood volume is small. The amount of blood lost by ordinary standards may be very minimal, but for the newborn infant it may prove to be exsanguinating. The abdominal approach is always used in this group of subjects for several reasons. The costal margin of the infant usually flares widely and is very resilient, which makes the diaphragm readily available for the repair. The abdominal approach permits the surgeon to examine the abdominal viscera for associated anomalies of development and the hernia is more easily repaired with the abdominal viscera delivered out onto the abdominal wall. The infant tolerates surgical evisceration very well, if the viscera are protected by a warm moist pack. This is our initial procedure in these patients, as well as in those with malrotation or intestinal atresia in whom early operation is mandatory.

In older children or in patients having an esophageal hiatus hernia with an associated short esophagus, the thoracic approach is

preferable. A congenital diaphragmatic hernia that has been present for some time may develop adhesions between the viscera and the pleura that are more easily severed by the thoracic approach. In any event, time has ruled out associated congenital anomalies of the intestinal tract, and the abdominal cavity is sufficiently large after a few months to accommodate the herniated viscera. If the child has survived for a time, the hernia cannot be massive and the quantitative replacement problem is not so great as in those subjects in whom immediate operation is required. In this group, the technical problems of repairing the diaphragmatic defect are more easily handled from above. In patients with a congenitally short esophagus with a thoracoabdominal stomach, the thoracic approach is always used. Whether one simply enlarges the hiatus and fixes the stomach, transplants the esophagus to a higher position on the diaphragm or gains increased length of the esophagus by dissection, the operation is almost impossible from the abdominal approach. This type of hernia does not give serious symptoms in the newborn and therefore the operation is performed upon older children and adults.

Preoperative and postoperative decompression of the gastrointestinal tract is a necessity in most types of diaphragmatic hernia. In recent years we have routinely done a gastrostomy after intestinal surgery on infants and used the gastrostomy tube for gastric suction, which, in turn, can be used for trial feedings. If a long intestinal tube has been passed preoperatively, the upper gastric and esophageal portion is simply pulled out of the gastrostomy wound and used in the same manner. This greatly reduces the problems in the postoperative period and is followed by a lowered incidence of tracheobronchitis and pneumonia. The few adults in whom we have used the gastrostomy tube for postoperative decompression of the upper gastrointestinal tract, as suggested by Farns, have counted the loss of the preoperative nasogastric tube as their greatest postoperative blessing.

These general principles apply to all adult types of diaphragmatic hernia and, in general, the thoracic approach is preferable. In the traumatic type of diaphragmatic hernia, the thoracic approach is always used unless it is advisable to explore all the abdominal viscera for associated injuries. If operation is delayed for some time after the injury, the thoracic approach is mandatory because of the high incidence of very dense adhe-

sions, frequently as high as the apex of the pleural space. Hemorrhage at the time of the injury may firmly encase an atelectatic lobe or lung in a fibrous envelope so that it will not expand without decortication and this can only be accomplished by the thoracic approach. Again, the hernia repair is more easily accomplished from above.

Finally, the repair of the diaphragmatic defect must adhere to sound surgical principles. The strong musculoaponeurotic margins should be approximated in the direction of the fibers of that portion of the diaphragm involved. When the margins of the defect cannot be approximated, several alternatives are available to the surgeon. The costal attachment of the diaphragm can be advanced superiorly to make a flat transverse diaphragm and thus gain additional musculoaponeurotic material for closure of the defect. The size of the hemithorax can be decreased at diaphragmatic level by resecting adjacent ribs. Although we have not had occasion to use it as yet, a sheet of wire mesh could be sewn into the defect and, by the time the mesh fragments, there should be a firm scar tissue lamina between the thoracic and abdominal cavities. Although this would undoubtedly stretch in time, it should resemble an eventration rather than a true hernia.

HERNIAS OF THE PELVIS AND PELVIC DIAPHRAGM

Except for the enterocele, hernias of the pelvic wall and pelvic floor occur rarely. The obturator canal and the greater sciatic notch are so well protected by musculoaponeurotic and fascial laminae that it is not surprising that hernias through these naturally occurring channels are rarely seen. On the other hand, the musculoaponeurotic structure of the pelvic diaphragm is frequently observed to be deficient in cadavers dissected routinely; this observation coupled with the fact that the pelvic floor is subjected to severe stresses and strains, especially in the parturient woman, would seem to indicate the pelvic diaphragm as an ideal location for the development of a hernia. This is not the case; in fact, hernias through the pelvic diaphragm are more rarely encountered than are obturator or sciatic hernias. When one considers man's upright carriage, the frequent pressures exerted in the pelvis and the frequency of severe trauma including fractures of the pelvic bones, the extreme rarity of pelvic hernias leads one to the conclusion that these her-

nias have their origin in a congenital defect. This view is possibly strengthened by an occasional report of one of these hernias occurring in an infant.

Our experience with pelvic hernias is confined to protrusions of fat and small peritoneal sacs without contents which we have not infrequently encountered in the examination of cadavers. The sole exception has been a patient having an obturator hernia containing a knuckle of incarcerated and strangulated ileum (Richter's hernia). With the exception of the enterocele, which is quite commonly observed, these hernias rarely reach a size at which they present a palpable tumor externally. Their diagnosis is usually established at operation for intestinal obstruction. Isolated instances have been reported for all of the pelvic hernias in which the sac was large and palpable externally.

The *obturator hernia* (Fig. 22) leaves the pelvis through the obturator canal along with the obturator nerve and blood vessels. The canal has very rigid margins and usually just accommodates the neurovascular bundle and a very small amount of areolar tissue that is continuous with the preperitoneal connective tissue. The superior portion of the canal is the obturator groove on the undersurface of the superior ramus of the pubic bone and the groove is converted into a canal by the tough obturator membrane. The canal is deepened and strengthened on either side of the membrane by the internal and external obturator muscles. It is inconceivable that a hernia could develop in the normal obturator canal. A congenitally large canal must be the etiologic basis. From cadaver observation, a pedunculated process of preperitoneal fat precedes, and is the entering wedge for, the peritoneal hernial sac. In the repair of this hernia, the peritoneal sac is extracted with ease and excised. The margins of the defect, however, cannot be approximated. A patch of adjacent internal obturator fascia can be turned as a flap to close the defect or a patch of wire mesh can be sewed circumferentially in place.

The *sciatic hernia* leaves the pelvis through the greater sciatic notch, either above the piriformis muscle or below it, in company with the corresponding group of gluteal blood vessels (Fig. 22). The *suprapiriformis* or *superior gluteal hernia* is said to be more common. The neck of the hernia is always intimately related to the trunks of the sacral plexus (Fig. 22). Here again, the

normal apertures for the egress of the gluteal vessels from the pelvis are so small that some congenital enlargement of these channels must be the underlying etiologic factor for development of sciatic hernias. If the inferior sciatic hernia follows the course of the internal pudendal artery, it is then called a *pudendal hernia*. From cadaver dissections, it would not appear that an adequate fascial flap is available for the closure of these defects and that one must avoid incorporating the trunks of the sacral plexus in the repair. It would appear that a patch of wire mesh would be an ideal material for the closure of sciatic hernial defects.

The *perineal hernias* protrude through the pelvic diaphragm between the musculoaponeurotic fibers of the levator ani muscles. Anterior perineal hernias advance into or through the urogenital diaphragm and posterior perineal hernias expand in the ischio-rectal fossa. The frequent observation of deficiencies in musculoaponeurotic structure in cadavers makes one wonder why these hernias are not more common. A cleft between the pubococcygeus and the iliococcygeus segments of the levator ani is commonly encountered. We have not observed a

the bone fragments nor have we observed postoperative pelvic hernias following combined abdominoperineal resection of the rectum or pelvic exenteration. These facts also indicate a congenital defect as the cause of these hernias. After removing the peritoneal sac and reducing fragments of peritoneal connective tissue, the musculoaponeurotic defect should be easy to close from below if the line of closure follows the direction of the musculoaponeurotic fibers of the levator ani.

Enterocele is a true hernia and must be differentiated from protrusions into the vagina due to attenuation of the rectovaginal septum and the vesicovaginal septum known, respectively, as rectocele and cystocele. In Figure 22, a small cystocele and a rectocele associated with an enterocele are shown for comparative study. Although an anterior enterocele occasionally occurs and begins in the uterovesical pouch, the most common enterocele is posterior and has its origin in the rectouterine pouch. The enterocele is not just a prolongation of the rectouterine peritoneal pouch but is a defect through it with the hernial sac dissecting downward in the rectovaginal septum. It bulges into the

posterior vaginal wall where it may be confused with a rectocele. The enterocele commonly occurs in conjunction with a rectocele, when thus associated it may be observed as a secondary bulge above the rectocele. If the enterocele pushes into the rectal ampulla instead of anteriorly into the vagina it is known as a *hedrocele*. The etiologic basis of the enterocele is a rent in the upper end of the rectovaginal septum into which a diverticulum of the peritoneum in the rectouterine pouch protrudes. The trauma incident to parturition is the usual precipitating cause, although an enterocele occasionally occurs in a nulliparous woman.

The enterocele rarely becomes incarcerated and the symptoms are essentially those of the rectocele—a heavy feeling in the perineum or a dull, aching type of pain. The

symptoms are aggravated when there is associated uterine procidentia. The average enterocele does not interfere with defecation, but a large rectocele usually results in difficulty in evacuating the rectal ampulla. The mechanical reason for this is demonstrated in Figure 22. The enterocele is a fairly common hernia; it is important that it be diagnosed correctly because the usual vaginal plastic operations will not effect a cure. A bulge in the mid or upper posterior vaginal wall that reduces with digital pressure only to reappear with a cough is presumptive evidence of an enterocele. The combined rectovaginal examination will easily differentiate it from rectocele. If a rectocele is present, the examiner's finger in the rectum will be seen in the vagina covered only by the thinned-out rectovaginal

HERNIAS of the PELVIS and PELVIC DIAPHRAGM

Figure 22. View of the left half of the pelvis after division in the midsagittal plane. The viscera have been removed except for the hollow tubes that perforate the pelvic diaphragm. Except for the peritoneal hernial sacs, all of the peritoneum, preperitoneal connective tissue and the muscular fasciae have been removed to show the apertures of the various pelvic hernias. The arrow with the * shows a small cystocele. The cystocele and rectocele are not true hernias but are shown in this figure for comparison.

nias have their origin in a congenital defect. This view is possibly strengthened by an occasional report of one of these hernias occurring in an infant.

Our experience with pelvic hernias is confined to protrusions of fat and small peritoneal sacs without contents which we have not infrequently encountered in the examination of cadavers. The sole exception has been a patient having an obturator hernia containing a knuckle of incarcerated and strangulated ileum (Richter's hernia). With the exception of the enterocele, which is quite commonly observed, these hernias rarely reach a size at which they present a palpable tumor externally. Their diagnosis is usually established at operation for intestinal obstruction. Isolated instances have been reported for all of the pelvic hernias in which the sac was large and palpable externally.

The *obturator hernia* (Fig. 22) leaves the pelvis through the obturator canal along with the obturator nerve and blood vessels. The canal has very rigid margins and usually just accommodates the neurovascular bundle and a very small amount of areolar tissue that is continuous with the preperitoneal connective tissue. The superior portion of the canal is the obturator groove on the undersurface of the superior ramus of the pubic bone and the groove is converted into a canal by the tough obturator membrane. The canal is deepened and strengthened on either side of the membrane by the internal and external obturator muscles. It is inconceivable that a hernia could develop in the normal obturator canal. A congenitally large canal must be the etiologic basis. From cadaver observation, a pedunculated process of preperitoneal fat precedes, and is the entering wedge for, the peritoneal hernial sac. In the repair of this hernia, the peritoneal sac is extracted with ease and excised. The margins of the defect, however, cannot be approximated. A patch of adjacent internal obturator fascia can be turned as a flap to close the defect or a patch of wire mesh can be sewed circumferentially in place.

The *sciatic hernia* leaves the pelvis through the greater sciatic notch, either above the piriformis muscle or below it, in company with the corresponding group of gluteal blood vessels (Fig. 22). The *suprapiriformis* or *superior gluteal* hernia is said to be more common. The neck of the hernia is always intimately related to the trunks of the sacral plexus (Fig. 22). Here again, the

normal apertures for the egress of the gluteal vessels from the pelvis are so small that some congenital enlargement of these channels must be the underlying etiologic factor for development of sciatic hernias. If the inferior sciatic hernia follows the course of the internal pudendal artery, it is then called a *pudendal hernia*. From cadaver dissections, it would not appear that an adequate fascial flap is available for the closure of these defects and that one must avoid incorporating the trunks of the sacral plexus in the repair. It would appear that a patch of wire mesh would be an ideal material for the closure of sciatic hernial defects.

The *perineal* hernias protrude through the pelvic diaphragm between the musculoaponeurotic fibers of the levator ani muscles. Anterior perineal hernias advance into or through the urogenital diaphragm and posterior perineal hernias expand in the ischio-rectal fossa. The frequent observation of deficiencies in musculoaponeurotic structure in cadavers makes one wonder why these hernias are not more common. A cleft between the pubococcygeus and the iliococcygeus segments of the levator ani is commonly encountered. We have observed

1
1
fragments nor have we observed postoperative pelvic hernias following combined abdominoperineal resection of the rectum or pelvic exenteration. These facts also indicate a congenital defect as the cause of these hernias. After removing the peritoneal sac and reducing fragments of peritoneal connective tissue, the musculoaponeurotic defect should be easy to close from below if the line of closure follows the direction of the musculoaponeurotic fibers of the levator ani.

Enterocoele is a true hernia and must be differentiated from protrusions into the vagina due to attenuation of the rectovaginal septum and the vesicovaginal septum known, respectively, as rectocele and cystocele. In Figure 22, a small cystocele and a rectocele associated with an enterocele are shown for comparative study. Although an anterior enterocele occasionally occurs and begins in the uterovesical pouch, the most common enterocele is posterior and has its origin in the rectouterine pouch. The enterocele is not just a prolongation of the rectouterine peritoneal pouch but is a defect through it with the hernial sac dissecting downward in the rectovaginal septum. It bulges into the

Congenital Malformations

By THOMAS H. LANMAN, M.D.

THOMAS HINCKLEY LANMAN was born in Cambridge in the shadow of Harvard University where he obtained his education. Graduated in medicine from Harvard Medical School, he was trained at the Massachusetts General Hospital and then became associated with the Children's Hospital in Boston where he became one of the pioneers in the surgery of children

The early diagnosis and the treatment of congenital malformations of the alimentary tract require a working knowledge of embryology. Without such knowledge the various malformations encountered, and there are a great variety, cannot be diagnosed early, nor can they be properly treated.

CONGENITAL ATRESIA OF THE ESOPHAGUS AND TRACHEOESOPHAGEAL FISTULA

Malformations and maldevelopments of the esophagus and trachea have become more widely and promptly recognized in recent years. With early recognition, more satisfactory and safer methods of treatment have been established.

One of the most dramatic advances in surgery is the treatment of congenital atresia of the esophagus with or without associated tracheoesophageal fistula. In Figure 1 the various types of atresia are illustrated. One

can reconstruct the symptomatology of the various types, the most important differentiation being whether or not there is a fistula between the esophagus and the air passage. About 90 per cent of these malformations are of type C. In this type the upper esophagus ends blindly and the lower end communicates with the trachea, usually at about the level of the bifurcation. In such cases, saliva or any liquid given for feeding rapidly fills this upper blind pouch. It then overflows and is inhaled into the trachea. This explains the coughing, choking and cyanosis so characteristic in the newborn infant who has this anomaly. Any attempt at feeding the child will produce these symptoms. If the airway is cleared, the infant's condition improves and may appear relatively normal, but each successive attempt at feeding is immediately followed by increasingly severe respiratory symptoms. Symptoms of this sort in the newborn baby should at once direct

septum. The enterocele can be felt as a thickening of the rectovaginal septum which disappears when the enterocele is reduced. The repair of the enterocele properly falls in the field of gynecology, but, in general, the neck of the peritoneal sac must be closed flush with the peritoneum of the cul-de-sac and the rent in the rectovaginal septum closed at the source of the hernia. This operation is usually combined with other plastic procedures performed by the vaginal route. If an enterocele is missed during a posterior vaginal wall repair, it will reappear to bother both the patient and the physician.

THE ALIMENTARY CANAL

Congenital Malformations

By THOMAS H. LANMAN, M.D.

THOMAS HINCKLEY LANMAN was born in Cambridge in the shadow of Harvard University where he obtained his education. Graduated in medicine from Harvard Medical School, he was trained at the Massachusetts General Hospital and then became associated with the Children's Hospital in Boston where he became one of the pioneers in the surgery of children.

The early diagnosis and the treatment of congenital malformations of the alimentary tract require a working knowledge of embryology. Without such knowledge the various malformations encountered, and there are a great variety, cannot be diagnosed early, nor can they be properly treated.

CONGENITAL ATRESIA OF THE ESOPHAGUS AND TRACHEOESOPHAGEAL FISTULA

Malformations and maldevelopments of the esophagus and trachea have become more widely and promptly recognized in recent years. With early recognition, more satisfactory and safer methods of treatment have been established.

One of the most dramatic advances in surgery is the treatment of congenital atresia of the esophagus with or without associated tracheoesophageal fistula. In Figure 1 the various types of atresia are illustrated. One

can reconstruct the symptomatology of the various types, the most important differentiation being whether or not there is a fistula between the esophagus and the air passage. About 90 per cent of these malformations are of type C. In this type the upper esophagus ends blindly and the lower end communicates with the trachea, usually at about the level of the bifurcation. In such cases, saliva or any liquid given for feeding rapidly fills this upper blind pouch. It then overflows and is inhaled into the trachea. This explains the coughing, choking and cyanosis so characteristic in the newborn infant who has this anomaly. Any attempt at feeding the child will produce these symptoms. If the airway is cleared, the infant's condition improves and may appear relatively normal, but each successive attempt at feeding is immediately followed by increasingly severe respiratory symptoms. Symptoms of this sort in the newborn baby should at once direct

Figure 1 Types of congenital abnormalities of the esophagus A, Esophageal atresia, no esophageal communication with the trachea. Under such circumstances the lower esophageal end is very apt to be quite short B, Esophageal atresia, the upper segment communicating with the trachea. C, Esophageal atresia, the lower segment communicating with the back of the trachea. Over 90 per cent of all esophageal malformations fall into this group D, Esophageal atresia, both segments communicating with the trachea. E, Esophagus has no disruption of its continuity, but has a tracheoesophageal fistula F, Esophageal stenosis. (CROSS The Surgery of Infancy and Childhood.)

the physician's attention to the possibility of this anomaly.

When the lower end of the esophagus communicates with the trachea, air readily finds its way into the stomach and bowel. This is easily demonstrated by a scout film of the chest and abdomen. The appreciation that about 90 per cent of these anomalies are of this type shows the futility of attempting, as was the case in earlier years, to treat this anomaly by a "preliminary" gastrostomy, for by this procedure anything introduced into the stomach immediately finds its way into the lungs.

The diagnosis is easily established by passing a small no. 10 urethral catheter down the esophagus. Its passage is stopped at the level of the atresia. An x-ray film of the chest and abdomen with the catheter in place will give visual evidence of the level of the atresia and in this type air will be seen in the stomach and upper bowel, demonstrating the communication between the trachea and the lower end of the esophagus. Contrast media are sometimes of help, but Lipiodol should be used, never a barium mixture. A certain amount of spill-over of the opaque material is to be expected and, if barium is used, it will cause a severe pulmonary reaction.

Prompt recognition of these characteristic symptoms should lead to early diagnosis. It is gratifying to observe that this anomaly is more frequently diagnosed than in the past. In the years 1926 to 1936, there were twenty-two patients with this anomaly admitted to the Boston Children's Hospital. In the following ten years, 1936 to 1946, there were 144 patients. From the above, one might argue that this anomaly had increased by about 500 per cent in ten years. This, of course, is not true and the increase must be

accounted for by the more frequent recognition of the condition. It seems probable that from 1926 to 1936 there must have been a comparable number of infants born with this anomaly. The anomaly was not reported as such and the death certificate probably had the diagnosis "pneumonia," which, indeed, these infants had and from which they died.

In the Boston Children's Hospital series, there was a high incidence of prematurity in the infants who had this anomaly. Fifty-two of the 259 patients studied weighed 5 pounds or less at birth; this is significantly higher than the prematurity rate seen in association with other malformations. This observation merits further study. Associated with this condition there is also a rather striking incidence of anomalies elsewhere in the body, many of which are of very serious consequence, particularly congenital heart disease, atresia or stenosis of the bowel and malformations of the anus and rectum. Some of these associated anomalies may require surgical treatment before or at the time of surgical repair of the tracheoesophageal anomaly. It is well, therefore, to consider the possibility of a coexisting abnormality in all these patients.

It is important to point out that the surgical repair of this anomaly should not be regarded as a true "emergency" procedure, for it has been found that spending twelve to twenty-four hours in overcoming the effects of dehydration and combating the varying degrees of pneumonitis which all these patients exhibit is useful and indeed

the bronchial tree through the fistula from the lower esophagus. Consuction of the

upper blind pouch by means of a small urethral catheter should be instituted to prevent the overflow of saliva from the upper blind pouch into the air passage. Intensive chemotherapy should be started at once. My colleagues and I have used a combination of penicillin and streptomycin. An oxygen tent is always helpful. It is of prime importance to have continuous nursing care, with particular attention to the maintenance of a clear airway.

As in any extensive surgical procedure in the young, means to maintain constant intravenous fluid administration should be established. This is best done by inserting a fine polyethylene tube through a cut-down incision over an ankle vein. This allows the administration of fluids and of blood as needed. It may be left in place for thirty-six hours and should, of course, be inserted before the operation. Since there is definite danger of phlebitis if the tube is left in place for more than forty-eight hours, it is wise to use another vein if the intravenous route is still needed.

A skilled anesthetist is essential. It has been found that the use of the intratracheal tube may result in a disturbing and even dangerous irritation of the larynx or trachea in these small patients. Also the intratracheal tube may allow too high a pressure within the alveoli, leading to pulmonary edema in the postoperative period. Cyclopropane-oxygen administered through a properly fitting face mask is the anesthetic of choice.

A direct transpleural attack on this anomaly with closure of the fistula and a direct anastomosis of the two ends of the esophagus is the preferred procedure. In earlier years this method of treatment did not seem possible and in some subjects the fistula was closed and an exterior esophagus constructed. For a patient suffering from cancer the construction of an exterior esophagus is justifiable, but to commit an infant to such a life is most undesirable and this procedure has been abandoned entirely since 1945. All patients are now submitted to a one-stage repair with closure of the fistula and primary anastomosis of the esophagus.

After direct anastomosis, some of the patients may be fed by mouth from the start. However, it is far safer to perform a temporary Stamm-type gastrostomy employing a self-retaining catheter, either at the time of the original operation or the next day. This procedure permits early and adequate feeding and allows better healing of the esoph-

agus. It is best done through an upper left rectus muscle-splitting incision.

Following surgery, these infants need plenty of oxygen in a moist, wet atmosphere. Suction should be available at all times. Chemotherapy is continued until all evidence of pulmonary infection has disappeared. Usually within a few days the child can swallow its own saliva. Feedings through the gastrostomy opening are started on the second day using a 10 per cent solution of glucose in appropriate amounts at short intervals and adding a milk formula by the fourth day. Caution must be taken not to give too large amounts at a time. The stomach in these patients is usually smaller than normal and any overdistention will cause regurgitation of the stomach contents up into the esophagus. The safest method is to give these feedings by the gravity drip method and to spend at least a half hour in each administration. Oral feedings may usually be safely started on the tenth postoperative day. By the end of three weeks the infant is able to take full feedings by mouth, at which time the gastrostomy tube is left in place but is clamped off. By the end of a month or six weeks, the gastrostomy tube may be safely withdrawn and the gastrostomy opening allowed to close spontaneously. The greatest postoperative dangers are the respiratory complications and until these are well under control the patient should remain in the hospital. However, in our series of patients, about 75 per cent of those surviving operation were discharged with safety at the end of three weeks.

It is important to keep these patients under observation for a number of months and to remember that even though they may swallow liquid food, they may have some later difficulty with solid food. Dilation is needed only when there is clinical evidence of stenosis. X-ray evidence alone is not a reliable guide.

CONGENITAL SHORTNESS OF THE ESOPHAGUS

Congenital shortness of the esophagus is always associated with the presence in the lower mediastinum of a segment of the stomach lying in the same axis as the esophagus. This segment is usually cylindrical in shape and is therefore sometimes not recognized as stomach by the roentgenologist. When exposed at operation or autopsy, however, the condition is obvious. The esophago-gastric junction (cardia) in an individual

with this condition lies at a level above the diaphragm, sometimes as high in the mediastinum as the arch of the aorta. Although there is sometimes a small upward projection of the peritoneum to form a short sac along the anterior surface of the thoracic segment of stomach, the condition is not, strictly speaking, a true herniation through the esophageal hiatus. This distinction must be made in order to permit the surgeon to choose the correct procedure if an operation becomes necessary.

Although it is sometimes compatible with the enjoyment of a normal existence, patients who have this anomaly have a much greater than normal tendency to develop esophagitis in the segment of esophagus just above the cardia. This complication may not be encountered until the patient reaches adult years or even old age.

Ulcerations frequently develop and the ultimate result of the destruction of mucous membrane is healing by cicatrization with subsequent stricture formation. Treatment by bougenage is sometimes successful in maintaining an adequate lumen. In certain patients, however, resection of the diseased area must be resorted to and can be performed with relative safety and complete relief of the condition by a left-side, trans-thoracic approach. It is an interesting fact that a relatively large proportion of patients

with a short esophagus, thoracic stomach and esophagitis or ulceration near the cardia have coexisting duodenal ulcer. These patients may have a particular disposition to ulcer formation.

CONGENITAL OR REDUPLICATION CYSTS OF THE ESOPHAGUS

These are rare in occurrence but may become so large that dysphagia results. In an occasional patient such a cyst may become infected and produce serious difficulties. Occasionally a cyst empties by discharging its contents into the lumen of the esophagus. A cyst can usually be removed from the wall of the esophagus by local excision in such a manner that the defect can be repaired without the necessity for segmental resection.

CONSTRICTION OF THE ESOPHAGUS BY ANOMALOUS OR ABERRANT VESSELS IN THE MEDIASTINUM

Constriction of the esophagus and trachea by an anomalous double aortic arch or by an aberrant innominate artery which arises from the left side of the aortic arch and passes across the esophagus to the right is a rare cause of congenital dysphagia. Division of one of the vessels which make up the vascular ring of a double aortic arch brings about immediate relief (Fig. 3). Compression of the esophagus by an aberrant right

Figure 2. A roentgenogram made after ingestion of barium, showing a large, rounded filling defect in the lower portion of the esophagus produced by a congenital enterogenous cyst of the esophageal wall.

the constriction by ligation and division of the anterior vessel

innominate artery, arising from the aorta at the point where the arch becomes the descending portion and passing usually behind the esophagus, rarely gives rise to dysphagia severe enough in degree to make surgical interference necessary. Difficulty in swallowing caused by this anomaly has acquired the name dysphagia lusoria.

CONGENITAL HYPERTROPHIC STENOSIS OF THE PYLORUS

Congenital hypertrophic stenosis of the pylorus is one of the most common conditions requiring surgical treatment in early life, but there is still some difference of opinion as to its true etiologic background. Grossly, there is marked hypertrophy of the circular smooth muscle fibers of the pylorus. The resultant mass is usually described as being of the shape and size of an olive; actually it is more spool shaped as its ends are not oval. The most striking characteristic of this mass is its firm, gristly almost cartilaginous consistency. The consistency is important in the diagnosis, for there is no doubt in the mind of the surgeon when he palpates the tumor of true pyloric stenosis. If he "thinks he feels a tumor," the chances are great that he is wrong. He may be feeling the liver's edge, the pole of the kidney or an edge of a muscle.

While there is no racial predisposition, there is a striking sex preponderance, far more so than in any other surgical condition found in this age group. Males are affected more commonly than females in a constant ratio of 4:1. This is of considerable significance in the differential diagnosis. The condition is more likely to occur in a first-born child than in subsequent siblings, but this is by no means as striking as the sex incidence. It may occur in more than one sibling; in our series there was one instance in which four siblings had this condition.

The symptoms are those of obstruction at the pylorus. The vomiting usually begins in the second or third week of life, rarely before the tenth day. The vomiting at first is not striking and may easily be considered as little more than the regurgitation so frequently occurring after feeding an infant. As the condition progresses, the vomiting becomes more and more forceful and though often spoken of as "projectile," "explosive" seems to be a better term. The mother will often volunteer a characteristic description of the vomiting and her statement should never be disregarded. In the well-established case, the vomiting will occur shortly

after each feeding. Of prime importance is the fact that the vomitus does not contain bile. With the increasing obstruction and vomiting, the infant will show the results of starvation. He fails to gain and later rapidly loses weight. There is a marked loss of subcutaneous fat, particularly noticeable about the orbits. There is loss of turgor in the skin which has a characteristic wrinkled appearance, especially marked in the face, neck and extremities. The infant is not "sick." He is extremely hungry and will nurse eagerly even after a bout of vomiting. The mother usually states that the child is constipated. This is not true; the stools are scanty and infrequent because little of the food intake reaches the bowel. One of the most characteristic features is the presence of vigorous waves of peristalsis in the upper abdomen. These waves are readily seen if the child is examined during a feeding and the more advanced the disease, the greater the loss of subcutaneous fat and the more prominent are these waves passing from left to right. The abdomen is not distended, as the obstruction is high, though there is usually a fullness in the epigastrium. The diagnosis is definitely established on palpation of the characteristic tumor mass in the right upper quadrant. With increasing experience, this tumor has been felt in over 95 per cent of our subjects. The firm, gristly tumor is most likely to be palpated just after the infant has vomited, at which time the abdominal wall relaxes. Palpation must be done slowly, patiently and with gentleness. Little will be learned by hasty, sudden palpation, especially with a cold hand.

In the average case, x-ray confirmation is not needed. In the unusual subject, it is simple and easy to give a small amount of a thin mixture of barium by mouth and, if true pyloric stenosis is present, the pyloric canal will appear to be greatly narrowed and lengthened, with dilatation of the stomach associated with deep waves of peristalsis.

In summary, then, this condition is manifested by vomiting which usually starts about the end of the second week of life and becomes increasingly frequent and more forceful. The vomitus does not contain bile. The infant shows progressive evidence of weight and fluid loss. The stools are scanty but otherwise normal. The infant is constantly hungry and this also helps to differentiate the vomiting and loss of weight from that caused by infections. The most significant finding, which with care and patience should be obtained in over 95 per cent of the

subjects, is the hard, firm tumor in the pyloric area

Intracranial injuries occurring during birth or a blood dyscrasia responsible for intracranial bleeding may cause vomiting in the newborn. In such infants, however, the vomiting is not characteristic of that due to an obstruction nor does it usually have a specific relationship to the taking of food. There are likely to be other symptoms of intracranial damage such as convulsions or a bulging fontanel and in such instances a spinal or subdural tap is indicated. The vomiting is likely to appear sooner after birth than when it is due to pyloric stenosis, as is also true of the vomiting caused by malformations of the esophagus. Congenital obstruction, however, in the region of the duodenum may show many of the characteristics of pyloric stenosis, but in this condition there is usually bile in the vomitus and this excludes the diagnosis of simple and true pyloric stenosis.

It is probable that there is an element of spasm in all cases of true pyloric stenosis, but the symptoms of pylorospasm alone are much less characteristic than are those of true pyloric stenosis. In pylorospasm the vomiting is as a rule not progressive, though it is often forceful and there are periods of remission. The child having pylorospasm often exhibits a generalized hypertonicity and his symptoms can often be entirely relieved by use of atropine and mild sedation. These drugs do not affect the symptoms in true pyloric stenosis.

Pyloric stenosis is in no sense a surgical emergency. It is always possible and desirable to take time to rule out the possibility of other organic bases for the vomiting, with a careful evaluation of the feeding program as regards its suitability for the particular infant.

Twenty-four to forty-eight hours may be well spent in getting the patient in good condition for operation. He needs, in addition to a 10 per cent solution of glucose for its caloric value, physiologic saline solution to make up the loss of chlorides caused by vomiting due to a high intestinal obstruction. Normal saline solution, 15 cc per pound of body weight, and 10 per cent aqueous so-

lution and the addition of hyaluronidase is helpful. If the red blood count is much below 4 million per cu. mm., transfusion of blood is useful, as there is likely to be a low plasma protein level; in such infants, 10 cc. of blood per pound of body weight at any one transfusion is the upper limit of safety. In the usual patient, however, blood transfusion is not needed. The fluid requirements are well fulfilled by the parenteral administration of glucose and saline solutions. Preoperatively, milk given by mouth is of little benefit and may indeed do harm. Since vitamin C is of considerable importance in promoting better healing of the wound, 25 mg. of ascorbic acid a day are routinely given.

The anesthetic of choice is ether administered by the open-mask method. This has been used in 98 per cent of our patients and there have been no deaths which could be attributed to this anesthetic. Atropine, 0.06 mg., is given preoperatively, but morphine should not be used. If the staff anesthetist has not had sufficient experience with the open-mask method in the infant patient, local anesthesia, supplemented with the use of a brandy-and-sugar nipple, may be safely employed, although it prolongs the operation and does not give as satisfactory relaxation as ether. The usual precautions in preserving the infant's body heat by appropriate covering of the arms and legs and using a hot water bottle under the back are essential. A small urethral catheter introduced through the nose into the stomach aids greatly in deflating the stomach.

The right upper quadrant gridiron incision is superior to all others. It allows prompt and solid healing and, if properly placed, permits adequate exposure of the pylorus. The incision should be about 3 cm. long, extend outward from the lateral border of the right rectus muscle and run parallel to and just below the liver edge. The costal margin is a less reliable landmark. The Ramstedt incision of the pylorus is made on the less vascular anterosuperior surface of the pyloric tumor. There is danger of entering the bowel at the duodenal end where the hypertrophied pyloric muscle fibers end abruptly. Should such an accident occur, the opening may be readily and securely closed with one or two fine silk sutures to invert the wound in the bowel. Under such circumstances, it is advisable to leave the gastric catheter in place and to provide constant suction for twenty-four to forty-eight hours after the operation. Nothing should be given by

be given subcutaneously if the sites or injection are changed frequently. For the subcutaneous injection, a 5 per cent aqueous solution of glucose is safer than a 10 per

mouth. Meticulous care in closing the peritoneum and abdominal wall is necessary.

In the first two or three days following operation, it is neither necessary nor desirable to give the normal amount of nutriment. It is, however, important to maintain the fluid intake. The plan of giving 3 ounces of fluid per pound of body weight per twenty-four hours is a useful guide.

The actual content of the formula may vary greatly, but the amounts given at any one time must be rather small at first. Although the schedule of feeding may be varied to meet the individual need, it is well to have some standard form of procedure so that the house staff and nurses may appreciate the usual routine. At the Children's Hospital, the following formula and feeding schedule have been found most useful.

FEEDING FORMULA

Evaporated milk	6 parts
Karo (red label) 50 per cent	1 part
Water	8 parts

FEEDING SCHEDULE

Beginning 4 hours after operation

1 oz.	5% glucose	every 2 hrs	3 feedings
1 oz.	formula	every 2 hrs	till 8 P M. day after op

1 1/4 oz formula every 2 hrs 6 feedings

Beginning second morning after operation

2 oz. formula every 3 hrs 8 feedings

Beginning third morning after operation

3 1/4 oz formula every 4 hrs 6 feedings

After the fourth or fifth day, fluid and aortic requirements can usually be met by oral feedings. Not infrequently there will be some postoperative vomiting. Should this occur, it is usually necessary only to reduce the oral intake in amount or to build up the intake more slowly.

With increasing knowledge, better anesthesia, adequate preoperative and postoperative care, the results of surgical treatment of pyloric stenosis have improved tremendously. In the decade following the introduction of the Ramstedt operation, the over-all mortality in this country was approximately 50 per cent. Since 1936, at our hospital, over 1500 infants have been treated, with a mortality of less than 1 per cent. An incomplete division of the pyloric muscle made necessary a secondary operation in four of these patients. There has been complete and lasting relief of the symptoms. We have patients who have been followed for as long as thirty-five years and as yet no late complications have been observed.

ATRESIA AND STENOSIS OF THE INTESTINE

Atresia of the intestine is a complete lack of intestinal continuity; stenosis is a narrowing of the intestine. Congenital atresia and stenosis of the small intestine are the result of an arrest in the development of the embryo at an early age. Prior to the fifth week of fetal life, the intestine has acquired a lumen lined with epithelium. Between the fifth and twelfth weeks the intestinal lumen becomes obliterated by epithelial concretion and is changed into a solid cord. By the twelfth week the solid cord has become vacuolized, the vacuoles have coalesced and the intestinal lumen has become re-established. Atresia is the result of an arrest in development during the solid stage (Fig. 4). The cause of such arrests in development is still a matter of surmise. Stenosis of the intestine represents an arrest of growth in a slightly later stage of development, namely, the stage of vacuolization, and is manifested by a septum across the bowel with a small perforation in it. There may be two blind ends, the proximal separated from the distal by a small, fibrous cord of varying length.

Atresia and stenosis may occur at any point in the small intestine but are most commonly found in the ileum, next in the duodenum and next in the jejunum; they may be multiple. Atresia and stenosis of the colon are rare lesions. Gross described only six colonic atresias in a series of 140 intestinal atresias observed in the Boston Children's Hospital, and only one stenosis in seventy-one patients with stenosis of the intestinal tract. In intestinal or colonic atresia, the bowel above the obstruction becomes dilated and that below remains collapsed. In the patient with atresia, the bowel below the obstruction appears like a small, hard cord, although, on examination, it is found to contain all the normal elements, including a lumen. This lumen, however, may be only large enough to admit a small probe. In patients having stenosis, the bowel below the point of obstruction is not as small as in those with atresia.

In the newborn infant the symptoms of atresia and stenosis are pain, restlessness, vomiting and lack of passage of normal meconium. On examination, abdominal distention, visible peristalsis or coils of intestine and evidence of shock and dehydration are apparent. Exceptions to these usual findings may be noted if the obstruction is in the duodenum. In such patients the vomiting

Figure 4 The septum across the duodenum: a, the result of the arrest of development at the solid stage; b, duodenojejunostomy for relief of the duodenal obstruction caused by a

may be so sufficiently effective that the stomach and duodenum are thoroughly emptied and consequently no abnormal distention or peristalsis is seen.

A roentgenogram taken without the administration of barium is of value in confirming the diagnosis (Fig. 5). The point of obstruction may be clearly outlined by the air in the dilated loop of intestine above it. The administration of barium to a patient with suspected atresia is not only unnecessary but is contraindicated, as the barium will block the small lumen of the intestine below the obstruction after an anastomosis has been performed and thus impede recovery. Another aid in confirming the diagnosis is the failure to find any keratinized cells in the stools.

When the diagnosis of congenital obstruction has been made, the patient is prepared for operation by parenteral administration of fluids in sufficient amounts to counteract dehydration, alkalosis or ketosis. In considering the operative measures to be employed, it is well to divide the various types into separate classifications, depending on the site of the obstruction. The obstructions in the duodenum are the first to be considered.

The intrinsic type of duodenal obstruction usually occurs in the third portion of this structure and it is often impossible, as well

as inadvisable, to attempt to determine whether the obstruction is due to stenosis or atresia. In either case the operation of choice is a retrocolic duodenojejunostomy. In a few subjects, because of too great technical difficulties in performing such a duodenojejunostomy, a gastrojejunostomy may be performed. This gastric operation is not satisfactory physiologically, because of the probable reflux of bile and duodenal contents, if the obstruction is beyond the ampulla of Vater, as it often is. If obstruction exists immediately distal to the pylorus, gastro-duodenostomy may be appropriate. If a membrane is present which obstructs the duodenum, it may be difficult or impossible to determine the site and cause of obstruction without opening the proximal portion of the duodenum and inserting an exploring finger downward in the duodenum. At times such an opening subsequently may be utilized in the performance of duodenojejunostomy. If an obstructing membrane is found, this may be excised or by-passed with an intestinal anastomosis. In exceptional cases, concomitant obstruction of the common bile duct may be present, under these circumstances, a simultaneous biliary intestinal anastomosis of an appropriate type is indicated.

For a patient who has stenosis or atresia lower down in the small bowel, a lateral

anastomosis should be performed. For this, the special technique recommended by Ladd is of great value. As shown in Figure 6, a rubber catheter is inserted in the distal lumen. The caliber of the ileum beyond the site of the obstruction is very small. The lumen of the gut has never been distended with meconium. By gentle distention of the distal gut with saline solution introduced through the catheter, the disproportion between the dilated proximal gut and the small undeveloped distal gut is lessened and the placing of the sutures becomes technically much easier.

In the after-care, great attention must be paid to maintaining the fluid requirements as well as the electrolyte balance and the serum protein levels of the patient.

Chemotherapy and antibiotic therapy in their various forms are an added safeguard and should be used in all these patients. It is important to emphasize, however, that they are by no means a substitute for the other important details of good surgical treatment, especially the establishment and maintenance of proper fluid and electrolyte balance. The use of chemotherapeutic agents within the peritoneal cavity should be abandoned. In these small patients there is danger of too sudden and too great a blood level of the agent employed and, instead of aiding in recovery, it may greatly

impede it or even result in a fatal outcome. The drug should be administered parenterally by the continuous intravenous route, which is best established before the actual operation is begun.

It is desirable that feedings be given by mouth as soon as possible, as this assists greatly in enlarging the lumen of the bowel distal to the site of the anastomosis. Saline enemas help to restore the large bowel to a more normal size and greatly assist in the restoration of bowel function.

With improved technique and particularly with improved preoperative and postoperative care, the prognosis is becoming more favorable. The nearer the obstructive lesion is to the pylorus, the better the chance for a successful operative result. In the Children's Hospital, from 1940 through 1952, recoveries were 57 per cent. In 1952 there were nineteen cases of atresia or stenosis with thirteen recoveries (68 per cent).

There is one rather striking finding in these cases which demands further investigation; this is the apparent association of mongolism with congenital obstruction in the duodenum. In reviewing our results, it has been found that about 25 per cent of the long-term survivors of the operative correction of duodenal atresia or stenosis are Mongolians. This figure is a disturbing one and has been confirmed by a report of similar cases from the Great Ormond Street Hospital for Sick Children in London. This hospital reports an incidence of nearly 30 per cent of mongolians in the subjects who survive.

Obviously, the diagnosis of mongolism cannot be established with certainty in the

Figure 5. Roentgenogram of a patient with atresia of the duodenum which shows clearly the point of obstruction without the administration of barium.

Figure 6. Method of using a soft rubber catheter to dilate, with saline solution, the narrow, undeveloped distal portion of the ileum at the time of side-to-side anastomosis.

first forty-eight hours of life. Efforts must then be continued to salvage an increasing number of patients born with this anomaly. The great challenge, however, is to find out why mongolism is apparently so frequently associated with this anomaly and also the etiologic basis of mongolism itself. Certainly if 25 to 30 per cent of the survivors of brilliant surgery done in the immediate neonatal period prove to be mongolians, the results can hardly be called brilliant for the patient or his family.

MALROTATION AND NONROTATION OF THE INTESTINE

Incomplete rotation, malrotation and non-rotation are terms used to describe various abnormal abdominal conditions which are the result of arrest in fetal development during or after the return of the midgut from the umbilical cord to the abdominal cavity. For an understanding of these conditions and for their successful treatment it is necessary to review some of the embryologic events which take place between the fifth and tenth weeks of fetal life.

At approximately the fifth week of fetal life the abdominal viscera grow much more rapidly than does the abdominal cavity, with the result that there is insufficient room within the cavity to accommodate the organs which are destined to be located there. Nature meets this situation by temporarily transferring the midgut, i.e., that portion of the intestine supplied by the superior mesenteric artery, into the base of the umbilical cord. In other words, a temporary and normal omphalocele occurs which lasts from the fifth to the twelfth week of fetal life. During this period the rate of growth of the abdominal cavity is accelerated so that by the tenth week it has acquired sufficient size to reaccommodate its organs.

The return of the midgut to the abdomen takes place in a particular way. The prearterial segment, or that portion of the intestine extending from the duodenum to the vitelline duct, returns first and passes from right to left behind the artery. The postarterial segment, or that portion of the midgut from the vitelline duct to the middle of the transverse colon, returns next and passes from left to right in front of the superior mesenteric artery.

The next stage of development consists in the descent of the cecum to the right lower quadrant and the fusion of the visceral and parietal peritoneum to give the mesentery of the small intestine its oblique attachment

to the posterior abdominal wall and the cecum and ascending colon their stabilizing attachment to the right side. An arrest in development may take place at almost any stage of this process (Figs. 7 and 8). Thus the cecum may remain on the left side, under the ensiform or in the neighborhood of the gallbladder (Fig. 9). These faulty positions may not of themselves be important or cause disturbance of the normal function of the bowel. A faulty position is important only when it causes pressure on one part or another of the bowel and results in obstruction. When obstruction occurs, the condition becomes of importance and necessitates relief by surgical intervention.

In instances in which the development has been arrested before the parietal and visceral peritoneum were fused, the midgut remains attached to the posterior abdominal wall by only a very small area at the origin of the superior mesenteric artery. Under these circumstances, a volvulus of the midgut is particularly liable to develop. The twisting of the midgut on itself with the origin of the superior mesenteric artery as a pivot is most likely to take place in a clockwise direction and may go through an arc of 360 degrees or more. Of course, the more it twists, the more complete is the obstruction and the greater the interference with the blood supply of the bowel.

The symptoms of the conditions resulting from faulty rotation or volvulus of the midgut are those of intestinal obstruction, namely, vomiting, pain, restlessness and evidence of shock and dehydration. These symptoms may appear soon after birth or, in contrast to the symptoms of congenital atresia and stenosis, may not appear for months or even years. They may be intermittent in character and of variable severity. On examination, abdominal distention and visible peristalsis are noted. It is to be remembered, however, that the obstruction takes place most commonly in the duodenum, so that the distention may be less marked than in other forms of obstruction lower down in the intestine. Distention, if present, is the result of the volvulus of the midgut. If the patient is not too acutely ill, a barium enema with roentgen ray examination may be used to confirm the diagnosis by showing the abnormal position of the cecum. In the still less severely ill patient, a barium meal and a series of roentgen ray examinations may yield useful information (Fig. 10).

The treatment of these conditions is sur-

Figure 7. A, Drawing showing the obstruction and dilatation of the duodenum caused by the mesenteric attachment of an unrotated and undescended cecum B, After completion of the operation for malrotation and nondescent of the cecum with volvulus of the midgut. The duodenum is exposed throughout its entire length and the cecum and appendix now lie in the left upper quadrant.

Figure 8 Malrotation of intestine with fibrous band obstructing terminal portion of duodenum.

Figure 9 Malrotation of cecum with coincidental Meckel's diverticulum of ileum (Mavo, C W, and Remington, J H Am J Surg, vol 72)

gical. The operation may be one of the most confusing in abdominal surgery and cannot be successfully carried out unless the embryologic development is kept in mind and the operation performed with a view to restoring normal physiologic function, regardless of normal anatomic relations.

Acidosis and dehydration are relieved preoperatively.

The method of surgical treatment to be described was first advocated by Ladd in 1933 and is the procedure of choice. In a patient without volvulus, the obstructed point is identified by the distended duodenum above and the collapsed bowel below it. The parietal peritoneum is incised, the cecum is transferred to the left upper quadrant and any constricting bands across the duodenum are severed so that the whole length of the duodenum is exposed and free. In a patient with associated volvulus of the midgut, out of the twist

untwisted until no interference with circulation is apparent. The duodenum is then exposed in its entirety to insure free func-

Figure 10 Roentgenogram made after ingestion of small amount of barium in a five-year-old child. It reveals dilatation and obstruction of the duodenum caused by fibrous bands secondary to incomplete rotation of the colon.

tion and reduce the chances of recurrence. The cecum is usually placed in the left upper quadrant.

In dealing with these patients with midgut volvulus, it must be remembered that reduction of the volvulus is only a part of the procedure necessary for cure. The abnormally placed cecum must be well freed from the right and toward the midline so that the entire duodenum is exposed. Experience has shown that reduction of the volvulus alone will almost invariably result in a recurrence of the symptoms.

In our series, however, there have been two patients in whom a volvulus of the entire small bowel below the ligament of Treitz, without involvement of the ascending colon, had taken place and was made possible by an abnormally long mesentery. In such patients, there has been no malrotation or nondescent of the cecum itself. In the treatment it is not only unnecessary but inadvisable to free the right colon and expose the duodenum. In these rare instances of volvulus of the whole small bowel, the duodenum is not obstructed.

of the cecum.

Since it is usually unwise to remove the

appendix at the time of the original operation, especially in those patients having associated volvulus, it must be kept in mind that appendicitis developing in these patients may produce quite unusual physical manifestations. In one child in our series who developed appendicitis some years following the operation for malrotation, the pain and tenderness were in the left epigastrium and it was from this region that the inflamed appendix was removed.

In the postoperative care, problems concerned with fluid balance must be uppermost in the surgeon's mind. Normal peristalsis ordinarily returns relatively soon after release of the obstruction and improvement may be striking. An indwelling intubation tube should be attached to a suction apparatus and checked frequently to be certain that the suction is working properly and that thick material within the intestine is not plugging the tube. Gentle irrigation of the tube may be required. When the surgeon is satisfied that peristalsis is normal and effective beyond the previously obstructed point, he may gradually withdraw the tube, since its prolonged use may result in esophagitis, difficulties in the eustachian tube and other unpleasant sequelae. Bowel movements should be established in a relatively normal fashion by the fourth postoperative day or sooner, gentle enemas of saline solution may be of some help. Early feeding of properly selected foods is allowed when the surgeon is satisfied that flatus is being expelled properly.

In earlier years, the mortality rate after this operation was forbidding, but more recently a decidedly favorable change has been noted. Since sepsis usually does not play a particularly large part in this type of obstruction, as the intestine need not be opened at any time, the deciding factors have been those of fluid balance and chemical replacement. The most distressing feature about this condition has been the relatively high rate of recurrence, as there is no reliable method of attaching the intestine or taking steps at the time of operation to guarantee that the patient will not experience recurrence. Gangrene of the intestine has been a large factor in the mortality rate associated with this condition.

In the treatment of 106 patients with malrotation in whom Ladd's operation was used, there was an 85 per cent survival rate in the group having no other congenital anomaly. There was a 43 per cent survival rate

in those with malrotation associated with some other abnormality.

MECKEL'S DIVERTICULUM

The vitellointestinal, or omphalomesenteric, duct is the communication between the midgut and the yolk sac during the first few weeks of fetal life. Persistence of this duct, or parts of it, in postnatal life results in various anomalies, one of which was first described by Meckel, in 1815, and has since been known as Meckel's diverticulum (Fig. 11). Meckel's diverticulum arises from the free, or antimesenteric, portion of the ileum, about 20 inches above the ileocecal valve. The persistence of this duct is estimated to occur in from 2 to 4 per cent of infants.

Though a Meckel's diverticulum may be present throughout life without causing symptoms, it is subject to a wide variety of pathologic changes and must always be considered a potential source of danger. It may remain attached to the umbilicus, with an unobstructed opening or intestinal fistula, it may remain attached to the umbilicus, without an unobstructed opening; it may become detached from the umbilicus and hang loose in the abdominal cavity or its tip may become attached to some other point in the peritoneal cavity and cause intestinal obstruction, it may become the site of acute inflammation, or diverticulitis, in many instances it contains aberrant gastric mucosa and is prone to show ulceration with hemorrhage or perforation, and, in some instances, it inverts itself into the lumen of the ileum and acts as the advancing point of an intussusception (Figs. 12 and 13).

The symptoms caused by Meckel's diverticulum are variable, according to the type of developmental error and the pathologic conditions arising from it. The unobstructed opening at the umbilicus gives the inconvenience and annoyance of any fecal fistula, with the difficulty of taking care of the fecal discharge and the irritation or digestion of the surrounding skin. The diverticulum which remains attached to the umbilicus may give intermittent abdominal pain of rather mild character referred to the umbilicus or more severe pain associated with vomiting, abdominal distention and visible peristalsis—in short, the signs and symptoms of intestinal obstruction.

The diverticulum which is not attached to the umbilicus may become adherent to almost any point in the abdominal cavity across a loop of intestine and cause intes-

Figure 11 a, Persistent omphalomesenteric duct with umbilical fistula; b, closure of duct with intussusception; c, closure of duct without attachment; d, Typical appearance of Meckel's diverticulum (Dixon, C. F., and Steward, J. A. S. Clin. North America, vol. 12)

tinal obstruction. When a Meckel's diverticulum is the site of acute inflammation, the signs and symptoms are similar to those of acute appendicitis and the erroneous diagnosis of appendicitis is frequently made. The importance of hemorrhage from the bowel as a symptom of Meckel's diverticulum must be emphasized.

Massive hemorrhage from the gastric mucosa in a Meckel's diverticulum is far more common than was once thought and is particularly likely to occur in small infants. In ten of the last thirty-one cases at the Children's Hospital, massive hemorrhage from the bowel was the presenting symptom. One of these patients was six years old, one was one year old and the other eight were less than a year old. Bleeding in varying degrees occurs in over 60 per cent of the subjects. If the ulceration perforates, the signs and symptoms are those of peritonitis and are

frequently preceded by a history of blood in the stools. If a Meckel's diverticulum is inverted into the lumen of the intestine, causing intussusception, the symptoms and signs are, of course, those of intussusception.

The treatment of Meckel's diverticulum is surgical and is aimed at relieving the variety of conditions which this appendage causes. Patients who have a massive hemorrhage should have immediate transfusion and operation. If the diverticulum is inflamed, early operation is indicated to prevent free perforation just as in acute appendicitis. If intestinal obstruction is present, it must be relieved and when intussusception is found, that must be reduced. It is desirable to remove the diverticulum in all subjects, except when there are conditions which contraindicate this procedure at the time of the first operation. Removal should be done through a transverse incision in the ileum at the base

of the diverticulum and the incision should be sewed up transversely so as not to obstruct the lumen of the ileum. It is important that the entire diverticulum be removed, as a common location for ulceration is at its base. There is always a temptation to remove a diverticulum as one would an appendix by tying its base and inverting its stump with a purse-string suture. This procedure should be condemned because of the probability that intestinal obstruction will result

from the narrowed lumen and because some of the diverticulum may be left.

In certain conditions, particularly those in which the Meckel's diverticulum is the cause of intussusception, it may be inadvisable to remove the Meckel's diverticulum at the time of the original operation. Each case must be judged on its own merits, but if the diverticulum is not removed at the first operation, it should be removed later, when conditions are more favorable. If bowel resection is needed, and this is especially likely in intussusception, the Mikulicz procedure is the one of choice. We have found that this operation is far safer in the over-all results than is primary resection followed by anastomosis.

Of the last 119 cases of Meckel's diverticulum at the Children's Hospital, including all types, 128 of the patients survived, the mortality rate being 14 per cent. Since 1940, there have been seventy-one of these patients with sixty-six survivors, the mortality rate being 7 per cent.

DUPLICATIONS OF THE ALIMENTARY TRACT

The term "duplications of the alimentary tract" is used in the hope of simplifying the nomenclature and because it more accurately describes the condition found than do other designations. Some of the terms employed to describe the same condition are: mesenteric cyst, enteric cyst, enterogenous cyst, diverticulum, giant diverticulum, ileum duplex, jejunum duplex and unusual Meckel's diverticulum.

It is now well established that although these malformations vary greatly in location, size and shape and may or may not communicate with the lumen of the bowel itself, they all present certain common characteristics.

After the solid stage in the development of the gastrointestinal tract, multiple vacuoles appear within the solid mass. These normally coalesce later so that the normal single hollow tube of the alimentary tract is formed. When duplications occur, Bremer believes that they are the result of the continued development of some of these vacuoles outside of the bowel. The duplications may or may not communicate with the lumen of the bowel itself.

Even though the duplications vary greatly in size and shape, their walls are at some point closely attached to the alimentary tract itself and, in the vast majority, their blood supply is connected with and is a continuous

Figure 12 Meckel's diverticulum producing classic intussusception of small intestine (Mayo, C. W., Miller, J. M., and Stalker, L. K. *Surg Gynec. & Obst.*, vol 71).

Figure 13 Greatly elongated Meckel's diverticulum with complete twist and formation of knot, obstructing ileum (Mayo, C. W., and Remington, J. H. *Am. J. Surg.*, vol. 72).

Figure 14 Duplication of small intestine (Johnston, J. B., Hallenbeck, G. A., Ochsner, A., and DuShane, J. W. Arch. Surg., vol. 68)

part of the blood supply of the adjacent intestinal canal. Duplications of the alimentary tract may occur anywhere from the base of the tongue to the rectum, but one-half are in the ileum itself (Fig. 14). Their walls have a serous coat with a mucous lining and a well-developed coat of smooth muscle. These bowel-like walls are easily recognized and help to differentiate the mass from the true lymphatic or chylous cysts. Lymphatic cysts are seen in the mesentery of the bowel and do not have a common blood supply with the bowel itself. If the duplication does not communicate with the lumen of the bowel, the contained fluid is usually a clear mucoid material secreted by the membranous lining, if it does communicate with the bowel, the contents are characteristic of those of the particular segment of the bowel involved.

A section through the wall will show a serous layer, a muscular layer and a layer of mucous membrane, as in the alimentary tract. The mucous membrane may be like that of the colon, the stomach, the duodenum or the ileum. The contents of the cyst may be mucoid fluid, sometimes chocolate colored and sometimes almost colorless. In some instances the fluid is sterile, but it may contain pus cells or colon bacilli. The chemical content of the fluid has been found simi-

lar to the succus entericus found in an isolated loop of bowel.

The symptoms vary according to the size and the situation of the malformation. When the cyst is in the chest, it causes coughing, cyanosis or dyspnea. If it is in the abdomen, there is pain and symptoms of acute or chronic intestinal obstruction may be evident. Hemorrhage from a peptic ulcer of the lining of the duplication may take place and may be sufficiently profuse to be fatal. Perforation with attending peritonitis has also occurred. A correct preoperative diagnosis is seldom made. It may be difficult to differentiate between this condition and Meckel's diverticulum, intussusception, an omental or mesenteric cyst and intestinal obstruction resulting from other causes.

In all our patients in whom duplication occurred in the abdomen, vomiting was a prominent symptom. Mild pain or abdominal discomfort was present in all and undernourishment or feeding difficulties were usually a part of the picture. Most of these patients had been under treatment because of "feeding problems."

The blood found in the stools may come from a peptic ulcer next to misplaced gastric mucosa in the lining of the duplication or from congestion of the intestine by pressure of the duplication. The tumor can usually be

felt and is likely to be rather more mobile than is a tumor of some other origin. Roentgen ray examination of the abdomen may be helpful but often is not. In one instance it showed free air in the peritoneal cavity, denoting perforation. Once it showed pressure on the stomach and on the colon. It may demonstrate partial obstruction which, of course, can be diagnosed by other means.

From our experience, duplication of the alimentary tract should be suspected in a child suffering from symptoms of partial intestinal obstruction in whom a freely movable tumor can be felt. It should be suspected also when blood is found in the stools, if the symptoms are less acute than those of intussusception and if the tumor is larger than would be expected of a Meckel's diverticulum.

The treatment of this condition is, of course, surgical. Because of the danger of obstruction, perforation or hemorrhage, the operation should not be unduly delayed. The operative technique is of importance and the operation usually involves resection of the loop of the bowel to which the duplication is attached.

It is a temptation for the surgeon who is confronted with his first patient having this anomaly to attempt to dissect the duplication away from the normal bowel. It is unwise to do this except in the rare patient in whom the duplication is detached from the normal bowel and has a mesentery of its own. Usually, the blood supply of the duplication and the blood supply of the bowel to which it is attached are the same and, if one dissects the duplication, the blood supply of the bowel is destroyed. Another factor which makes it unwise, or indeed impossible, to dissect the duplication from the normal bowel is that there is no line of cleavage between the two. The partition between the duplication and the normal bowel consists of two layers of mucous membrane with the muscle layers between. It is almost impossible to effect separation without perforating the lumen of one or both structures.

If operation is undertaken prior to the occurrence of infection, perforation or severe hemorrhage, the results have been increasingly good. Of the last sixty-eight duplications treated at the Children's Hospital, thirty-five were in the duodenum, jejunum or ileum. The mortality from 1928 to 1940 was 27 per cent, but in the last twenty patients there have been no deaths.

OMENTAL CYSTS

Congenital cysts of the omentum are probably caused by obstruction of lymphatic channels. They are thin walled, usually rounded, may be small and embedded within the omentum itself, or they may attain a huge size.

There is a history of a slowly enlarging abdomen, usually without pain, and on abdominal examination the cyst may be moved from side to side and there is evidence that it contains fluid. The treatment is simple and involves only excision. If the cyst is extremely large, the entire omentum may have to be removed, but it is usually possible to dissect out the usual cyst and preserve a part, or all, of the omentum itself.

MESENTERIC CYSTS

These may arise in any part of the mesentery or the mesocolon and, like omental cysts, they may be enormous. They grow slowly and produce little in the way of symptoms unless, when large, they give moderate abdominal pain associated with vomiting. As they become large, there may be some loss of appetite and failure to gain weight. Rarely the symptoms of acute intestinal obstruction occur, particularly if the cyst is in the free border of the mesentery, where, by greater mobility, it may compress or angulate the bowel. The cyst, if large, can usually be palpated as a soft, fairly well-defined fluctuant mass. As the usual location is in the jejunum or ileum, this mass, when so located, is more freely movable in a lateral than in a vertical direction, as compared with an omental cyst.

Unlike duplications, these cysts can usually be safely dissected out from the mesentery itself and this is the preferred method of treatment. There is not a common blood supply to these cysts and the adjacent bowel and a good line of cleavage is usually found. The cysts can be dissected from the intestine or colon without impairing the blood supply to the bowel. After removal, there may be a large defect in the mesentery, which should be closed with interrupted sutures. The results are very good.

ANNULAR PANCREAS

Constriction of the second portion of the duodenum may be caused by a maldevelopment of the pancreas. The degree of obstruction will vary with the extent of this anomaly. The head of the pancreas is in its usual position, but two branches or arms of pancreatic tissue enfold the duodenum at this

point These arms are usually fused and completely encircle the duodenum The symptoms are the same as those of congenital intrinsic stenosis in this area This anomaly is not infrequently associated with other congenital defects and, if so, the prognosis will depend to a large extent on the seriousness of the associated defects.

Annular pancreas is best treated by establishing a duodenojejunostomy This method has been used successfully since 1942 and it appears to be the ideal form of surgical correction. When done properly, it relieves the duodenal obstruction without interfering with the normal function of the stomach and the biliary tract and it does not include the dangers of cutting pancreatic tissue. Of the last ten patients so treated in our hospital, six are alive and well; four died, but death in three of these was caused primarily by other anomalies.

MECONIUM ILEUS

It is now recognized that intestinal obstruction in the newborn caused by impacted meconium is the result of a generalized disease. There is a marked disturbance and deficiency in the secretion of the pancreatic enzymes and also an abnormality of the mucus-secreting glands in both the alimentary and respiratory tracts. It is important to realize that in addition to the disturbance of pancreatic function which has been appropriately called fibrocystic disease of the pancreas and which results in these abnormal features in the meconium, there are also complications resulting from abnormal secretion of mucus elsewhere in the body, which has been termed mucoviscidosis This mucus is abnormally thick and viscid and often leads to severe pulmonary complications.

The intestinal symptoms caused by meconium ileus are similar to those of intestinal obstruction from other causes The vomiting begins early and is of a progressive type. The vomitus is at first clear but later becomes dark, as abdominal distention progresses. In this condition, one of the important and characteristic physical findings is the presence of a firm mass or masses palpable within the bowel itself, these masses being the thick, inspissated meconium.

X-ray findings are often characteristic. Obstruction will be demonstrated in the lower ileum, but the proximal distended loops will vary greatly in the degree of distention This variation in size is seldom found to be striking in the patient with an ordinary in-

testinal obstruction. The x-ray picture of the impacted meconium itself is quite characteristic The mottled or granular appearance is seldom noted in subjects with intestinal obstruction of other causes. Although the above characteristics are not always present, the evidence of intestinal obstruction is usually so clear that the indications for operative treatment are unmistakable.

There are occasional patients in whom the evidence of obstruction is not severe and it is sometimes possible in these subjects that the condition will resolve itself by the use of cleansing enemas and the giving of pancreatic enzymes by mouth. But the great majority require surgical treatment. After many and discouraging methods of surgical attack, the present treatment of choice is a Mikulicz resection with a double-barreled ileostomy. It is necessary to resect the greatly distended portion of the terminal ileum, for it is in this area that the meconium is greatest in amount and is thickest in character. The double-barreled ileostomy allows de compression of the intestine, permits flushing out of the terminal ileum and colon and the giving of pancreatic enzymes By this method an increasing number have been relieved successfully of their obstruction and it is hoped that the results will be even better in the future. It is important, however, to remember that the intestinal obstruction is only part of the picture. The child has a severe and chronic nutritional disturbance resulting from the pancreatic insufficiency and has frequently severe pulmonary damage resulting from the generalized mucoviscidosis The poor nutrition in these children is best compensated for by the addition of a fortified casein hydrolysate such as Nutramigen. This is added to the formula. The caloric value in the diet must be increased to about 50 per cent above that offered a normal infant of the same age. The vitamin intake should be high and it

at which time the crushing clamps can be used on the septum and thus intestinal continuity is re-established. Later the small ileostomy fistula may be safely and simply repaired surgically. These patients, however, demand a long period of careful medical observation through the following months and years.

Of twenty-two patients successfully operated upon in recent years, eight have succumbed to a severe respiratory distur-

or to pulmonary infection, or both, within a few months after operation.

HIRSCHSPRUNG'S DISEASE

In recent years there have been changes of fundamental importance in the concept and treatment of this disease. The work of Swenson and others has clearly shown that the true pathologic process of this disease is located in the undilated portion of the rectosigmoid and not in the dilated and hypertrophied part of the large bowel.

The present concept, which is supported by microscopic examination of the bowel wall, is that of a deficiency in the ganglion cells of the myenteric plexus in this narrowed area in the rectosigmoid. There is great interference with normal peristalsis in this area and this causes, in effect, an area of obstruction. The tremendous hypertrophy and dilation above it is the result of Nature's effort to force the fecal stream through this area where there is no true peristaltic action. The present-day treatment, then, is aimed toward the removal of this abnormal and narrow area instead of procedures directly concerned with the dilated portion itself.

As Hirschsprung's disease is a true congenital lesion, symptoms characteristically appear shortly after birth or in early infancy. This helps in differentiating the disease from the acquired megacolon seen in older children. In the latter condition, although there may be a compensable dilation and hypertrophy of the large bowel, the symptoms of chronic constipation usually do not appear until after the second year of life.

Hirschsprung's disease seems to be far more common in boys than girls and the history is that of long-continued, progressive and obstinate constipation. With this, there is marked and progressive enlargement of the abdomen. There is evidence of a very poor nutritional state and, in extreme cases, there may be interference with breathing and even circulatory embarrassment caused by the increasing upward displacement of the diaphragm. Vomiting and pain are seldom encountered, but it is well to remember that there may be attacks of "diarrhea." This paradoxical diarrhea occurs because only the liquid contents of the ileum can be passed around the solid impacted fecal masses in the colon. On rectal examination there is evidence of obstruction or stenosis in the rectum and in this area there is "hard" material, even though it is felt higher up. It is

important to note that mention of this last observation appeared in Hirschsprung's original article. The clinical picture varies a great deal, but the usual case is progressive and, as operative treatment is now so effective, it is advisable for most patients before too long a time has elapsed.

New examination should be made with some caution. A thin barium mixture is advisable. The diagnosis is often suggested by a plain film which shows the markedly distended colon, much gas and unplaced fecal material. Examination following a barium enema will allow visualization of the terminal 6 to 11 inches of the lower bowel in the oblique view and it is here that the narrowed caliber of the lumen is usually found. Views taken only in the anteroposterior plane will not demonstrate this area because of the overlying distended bowel.

Excision of the aganglionic area, with an anastomosis of the pull-through type of Swenson, has given extremely gratifying results. In seventy patients so treated, there were two deaths, but the surviving seventy-eight subjects have been followed for periods of from one to five years. They have excellent bowel control, take a normal diet and have progressed normally in growth and development. In two patients there was troublesome hypospadias of the bladder. This may have existed before operation or may have been the result of the operative procedure itself. As there may be some associated neurologic defect in the bladder of these patients, it is important to evaluate the bladder function in all subjects before operation, particularly in regard to the presence or absence of residual urine.

MALFORMATIONS OF THE ANUS AND RECTUM

Malformations of the anus and rectum are varied in type and are frequent enough to be of considerable importance. The variation in type depends on when and where the arrest in development of the primitive gut occurred and is intimately associated with the development of the urogenital sinus. In the early embryo, the cloaca is a cavity which includes both the intestinal tract and the urogenital tract. These two become separated by a downgrowth of mesoderm and this separation is normally completed at about the seventh week. In the further development, there is a division in this area into the urogenital membrane anteriorly and the anal membrane posteriorly. About the time of separation, there appears an external

point. These arms are usually fused and completely encircle the duodenum. The symptoms are the same as those of congenital intrinsic stenosis in this area. This anomaly is not infrequently associated with other congenital defects and, if so, the prognosis will depend to a large extent on the seriousness of the associated defects.

Annular pancreas is best treated by establishing a duodenojejunostomy. This method has been used successfully since 1942 and it appears to be the ideal form of surgical correction. When done properly, it relieves the duodenal obstruction without interfering with the normal function of the stomach and the biliary tract and it does not include the dangers of cutting pancreatic tissue. Of the last ten patients so treated in our hospital, six are alive and well, four died, but death in three of these was caused primarily by other anomalies.

MECONIUM ILEUS

It is now recognized that intestinal obstruction in the newborn caused by impacted meconium is the result of a generalized disease. There is a marked disturbance and deficiency in the secretion of the pancreatic enzymes and also an abnormality of the mucus-secreting glands in both the alimentary and respiratory tracts. It is important to realize that in addition to the disturbance of pancreatic function which has been appropriately called fibrocystic disease of the pancreas and which results in these abnormal features in the meconium, there are also complications resulting from abnormal secretion of mucus elsewhere in the body, which has been termed mucoviscidosis. This mucus is abnormally thick and viscid and often leads to severe pulmonary complications.

The intestinal symptoms caused by meconium ileus are similar to those of intestinal obstruction from other causes. The vomiting begins early and is of a progressive type. The vomitus is at first clear but later becomes dark, as abdominal distention progresses. In this condition, one of the important and characteristic physical findings is the presence of a firm mass or masses palpable within the bowel itself, these masses being the thick, inspissated meconium.

X-ray findings are often characteristic. Obstruction will be demonstrated in the lower ileum, but the proximal distended loops will vary greatly in the degree of distention. This variation in size is seldom found to be striking in the patient with an ordinary in-

testinal obstruction. The x-ray picture of the impacted meconium itself is quite characteristic. The mottled or granular appearance is seldom noted in subjects with intestinal obstruction of other causes. Although the above characteristics are not always present, the evidence of intestinal obstruction is usually so clear that the indications for operative treatment are unmistakable.

There are occasional patients in whom the evidence of obstruction is not severe and it is sometimes possible in these subjects that the condition will resolve itself by the use of cleansing enemas and the giving of pancreatic enzymes by mouth. But the great majority require surgical treatment. After many and discouraging methods of surgical attack, the present treatment of choice is a Mikulicz resection with a double-barreled ileostomy. It is necessary to resect the greatly distended portion of the terminal ileum, for it is in this area that the meconium is greatest in amount and is thickest in character. The double-barreled ileostomy allows decompression of the intestine, permits flushing out of the terminal ileum and colon and the giving of pancreatic enzymes. By this method an increasing number have been relieved successfully of their obstruction and it is hoped that the results will be even better in the future. It is important, however, to remember that the intestinal obstruction is only part of the picture. The child has a severe and chronic nutritional disturbance resulting from the pancreatic insufficiency and has frequently severe pulmonary damage resulting from the generalized mucoviscidosis. The poor nutrition in these children is best compensated for by the addition of a fortified casein hydrolysate such as Nutramigen. This is added to the formula. The caloric value in the diet must be increased to about 50 per cent above that offered a normal infant of the same age. The vitamin intake should be high and it is desirable to use vitamins which are water miscible. It is seldom necessary to keep the ileostomy stoma open more than three weeks at which time the crushing clamps can be used on the septum and thus intestinal continuity is re-established. Later the small ileostomy fistula may be safely and simply repaired surgically. These patients, however, demand a long period of careful medical observation through the following months and years.

Of twenty-two patients successfully operated upon in recent years, eight have succumbed to a severe nutritional disturbance

Figure 16. Types of fistulae encountered in male patients. 1, Rectovesical fistula. 2, Rectourethral communication. 3, Rectoperineal fistula (the opening being in front of the area where the anus should normally open) (Gross: *The Surgery of Infancy and Childhood*)

paired from below. If it is higher than that, it can usually not be repaired from below and, in such instances, sigmoidostomy can be done and the malformation may be repaired later when the child is one or two years of age. This procedure is probably the safer one if the facilities of the hospital or the experience of the surgeon is not ideal. But with the proper facilities and a surgeon who is familiar with this type of work, it is our opinion that such patients, if in good condition, should be treated immediately by the combined abdominoperineal approach.

As noted above, there is a very high incidence of associated fistula either with the skin or with the genitourinary tract. These complications are most likely to occur in association with the type 3 and type 4 anomalies and there is a much higher instance of rectourethral and rectovesical fistulae in the male than in the female. Commonly the associated fistulae in the female are those to the perineum just anterior to the anus or to the vagina. The presence of these fistulae in the male is readily recognized in the usual case. If the fistula communicates with the perineum, it is seen that the meconium comes out in small quantities anterior to the anal pit. If it communicates with the bladder or urethra, meconium will

be noted in the urine. The most frequent error in early diagnosis in the female is that of a fistula which empties close to, or actually into, the vagina. In such patients, meconium may appear to be coming normally from the rectum. The temperature, supposedly taken by rectum, is actually taken by inserting the thermometer in the fistula.

These complicated anomalies were poorly handled in the past, but a recent review shows that a satisfactory result can be obtained in well over 90 per cent of the patients and that the anus will function normally. It has also been possible to cure satisfactorily in a single operation well over 90 per cent of the patients with associated high fistulae. However, it is much better, if ideal facilities are not available, to do a temporary sigmoidostomy. It is extremely difficult to do a combined abdominoperineal repair in a patient who has had a previous unsuccessful operation. It is also important to call attention to the fact that anomalies of the anus and rectum are found to have other associated anomalies in about 40 per cent of the patients. In many instances another anomaly was the cause of death, among these fatal conditions being congenital heart disease, atresia of the intestine and atresia of the esophagus.

opening for the urogenital sinus and posteriorly there is an in-pocketing at the anal pit, which continues until the proctodeum meets the rectum. When the anal membrane ruptures at about the eighth week, there is a continuous passage from the hindgut to the outside.

As will be seen in Figure 15, there are four main types of anomaly and the treatment of these four types will be briefly outlined later. It is important to remember that in all types the anal sphincter muscle develops from the regional mesenchyma and is therefore not dependent on the maldevelopment of the bowel itself. This is fortunate because the sphincter muscle is of great importance in the repair of these anomalies.

Unfortunately, imperforate anus of the four types shown in Figure 15 is, in over 70 per cent of the cases, associated with a communication between the bowel and either the perineum or the genitourinary system. Figures 16 and 17 illustrate the common types of associated fistulae found in the male and in the female. The symptoms will vary greatly and will depend on the type of anomaly and, more important, on whether or not there is an associated fistula.

In patients without fistulae, the symptoms will depend on whether there is merely stenosis or whether there is, in fact, an imperforate anus. Those with type 1 abnormality have symptoms which will vary with the degree of stenosis and in some this stenosis does not give very marked symptoms until weeks or months following birth, when the bowel contents become more solid. In types 2 and 3 abnormalities, there is, of course, complete obstruction and the symptoms are obvious. Every newborn child, however, should be carefully examined at birth to see whether the anus is perforate and, if not, early and effective treatment

can be started. It is only in type 4 abnormality, in which there apparently is an anal opening, that the true condition is likely to be overlooked. In our series, for example, those with type 2 and type 3 abnormalities are seen within the first twelve hours of life, whereas those with type 4 may be brought to the hospital on the third or fourth day, sometimes even later.

In patients with type 1 abnormality, repeated dilations are usually enough to establish normal function. Dilatation is best done at first with graded metal dilators, later, the little finger can be employed with great advantage. Dilatation can be done by the mother if she is properly instructed. It is of great importance to keep these patients under observation for at least two years.

In patients with type 2 abnormality, the treatment is the same except that the membrane which closes the opening of the bowel must be incised. Incision alone is not enough and frequent observation with necessary dilations must be insisted on.

The treatment of patients having type 3 abnormality depends on the distance the blind pouch is from the anal skin. This distance can readily be determined by making an x-ray examination of the abdomen and pelvis with the patient head-down and with a small metal marker on the anal pit. This will show how far the gas in the obstructed bowel is from the skin itself. It must be pointed out that in such an examination the gas within the bowel may not have distended the bowel to its most distal point until after eighteen or twenty-four hours following birth. After this time the x-ray film will be a very accurate method of determining the position of the blind pouch. If the blind end is within 1.5 cm. of the anal pit, it can in most instances be successfully re-

Figure 15. Types of anal and rectal abnormalities. Type 1, Stenosis at the anus. Type 2, Imperforate anus. Obstruction only by a persistent membrane. Type 3, Imperforate anus. of sufficient of these vessels to carry a good supply of blood to the cut edge. Special mention should be made also of the relation of the esophagus to the thoracic duct, because of the serious prognosis of chylous hydrothorax which results from an unrecognized injury to that structure.

The venous system of the esophagus, with the exception of the lower portion, empties by way of the hemiazygos and azygos veins into the superior vena cava. Blood from the lower third of the organ enters the portal system through branches of the left gastric veins and the branches of the vasa brevia of the splenic vein. This communication between the systemic and portal circuits has great clinical importance in the production of varicosities of the esophageal and upper gastric veins.

The lymphatic drainage from the cervical portion and to some extent the superior mediastinal segment of the esophagus is to the large groups of lymph nodes in both sides of the neck. The drainage from the remainder is principally downward. The main lymphatic channels empty into the superior mediastinal nodes, the nodes about the hila

of both lungs, the lower mediastinal nodes, including those in the pulmonary ligaments, the subdiaphragmatic paracardial nodes and the group which lies in relation to the branches of the left gastric vessels along the lesser curvature of the stomach (Fig. 19).

Finally, it is important for the surgeon to keep in mind that the esophagus, because of its fragile structure and lack of serous covering, must be handled with much greater gentleness than the stomach or intestines. Its musculature, the greater portion of whose fibers are longitudinal, is delicate and does not hold sutures well. The mucosa is the toughest layer of the esophagus and much of the strength of an esophageal anastomosis depends upon the integrity of this layer.

The function of the esophagus consists almost entirely in conveying food and liquids from the pharynx to the stomach. A voluntary contraction of the pharyngeal musculature and the associated muscles of the tongue and floor of the mouth initiates deglutition and forces the material which is being swallowed downward into the esophagus. An associated nerve impulse brings about relaxation of the cricopharyngeus muscle. Once the ingested matter has entered the esophagus, two factors are brought to bear upon its further passage to the stomach. The effect of gravity is most important in

The Esophagus

By RICHARD H. SWEET, M.D.

RICHARD HARWOOD SWEET was educated at Columbia University and at Harvard Medical School where he now is on the faculty. Trained in general surgery, he has the ability to apply general surgical principles to the special physiologic and anatomic conditions found within the thoracic cavity. He has made many original contributions to esophageal surgery.

Progress in the surgical management of disorders affecting the esophagus is a modern development. Although several factors were involved in the delay, the most significant was the failure until recent years to overcome the difficulties presented by the necessity of operating through the open thorax. Of particular importance was the solution of the problems of maintaining control of the expansion of the lung and of securing an adequate degree of oxygenation of the blood during the operative procedure and the early recovery period. The resolution of these difficulties is the result of the utilization of knowledge of the physiology of the chest, which has made it possible to approach the esophagus with as much safety as any other portion of the alimentary tract.

Other difficulties which had to be overcome have yielded to the application of knowledge accumulated from many sources and applied first in other branches of surgery. The great progress which has been made in the field of nutrition has made it possible to overcome to some extent the effects of anemia and emaciation which result from the starvation produced by an obstructing lesion. As a result, many patients whose condition would formerly have been considered a contraindication to surgical treatment can now be operated upon successfully. Furthermore, the utilization of this knowledge has improved the management of the

postoperative period so as to minimize the incidence of complications.

Of great importance likewise in the progress of esophageal surgery is the almost complete elimination of the element of infection, which formerly was responsible for the majority of complications and postoperative deaths. This result has been brought about by the routine use of appropriate antibiotics in addition to the improvements in operative technique and the general management of the case as a whole.

For the surgeon, a thorough knowledge of the topographic relations of the esophagus is important. The esophagus in its course from the pharynx to the cardiac orifice of the stomach traverses three important regions of the body: the neck, the thorax and the abdomen. In its course it assumes an important relation to such structures as the trachea, the thyroid gland, the aorta, the great vessels as they ascend into the neck, the pericardium, the inferior pulmonary veins, the azygos and hemiazygos veins, the vagus nerves with their recurrent laryngeal branches, the thoracic duct, the diaphragm and the vertebral column.

Of vital importance to the surgeon likewise is realization of the fact that the arterial blood supply of the esophagus (Fig. 18) is strictly segmental in distribution, so that when a resection is performed, adequate provision can be made for the preservation

such as this holds enormous quantities of food and emits only small amounts at a time into the stomach. Patients sometimes discover that by straining or with changes in position, and often by taking large draughts of liquid, they can force some of the food down. But pain resulting from spasm is a rare occurrence.

In the remaining one-third of patients, the esophagus, though dilated, never assumes the gigantic proportions of the first type. Furthermore, in sharp contrast with the first type in which the muscle layer at the distal end is atrophic, the lower segment is not much narrowed and shows a striking degree of hypertrophy of the circular muscle fibers. Above this level the esophagus, though much larger than normal, never reaches the enormous size of the first type. When observed under the fluoroscope, instead of being atonic, it appears hyperactive but with erratic peristalsis and often antiperistaltic waves extending the entire length (Fig. 21). Patients with this form of the disease, at least in the early phases, experience cramp-like pain of esophageal reference usually initiated by eating.

Figure 20 Achalasia of the esophagus, type 1 comprising about two-thirds of the cases. Enormous dilatation, atrophic lower segment, absence of spasm or pain, no peristaltic activity.

In both types when the disease is of long standing, and particularly in elderly patients, repeated aspiration of stagnant esophageal contents into the trachea and bronchi may lead to pulmonary complications such as atelectasis, pneumonitis and fibrosis. Although many of the patients are able to maintain a satisfactory state of nutrition, there are those who become emaciated and require urgent treatment to relieve them.

Patients with each type of the disease have been observed over long periods without changes in the character of the condition and there is no evidence that one is actually the precursor of the other.

As with any lesion which causes a partial narrowing of the esophagus, the degree of obstruction is frequently increased in response to emotional tensions experienced by the patient, but there is no evidence that this disease is basically psychosomatic in origin. In fact, the etiology is unknown. There is always found, however, a diminution or an absence of the ganglion cells of Auerbach's plexus involving the entire length of the esophagus.

This alteration in the intrinsic nervous mechanism of the esophagus is in some way responsible for the disturbed neuromuscular

Figure 21 Achalasia of the esophagus, type 2 comprising about one-third of the cases. Moderate dilatation, hypertrophy of circular muscle layer of the lower segment, spasm and pain experienced; peristalsis active but abnormal.

the case of liquids, but for the passage of solids, active waves of peristalsis play an important role. The entry of food into the stomach may be delayed temporarily by a sphincter-like activity of the circular musculature of the lower esophageal segment. There is no true sphincter muscle of the cardia.

DIAGNOSTIC METHODS

The most frequent symptom which points to the esophagus as a source of difficulty is some disturbance of deglutition, often so slight at first that the patient may give it little consideration. Other symptoms, such as eructation of material swallowed, pain, loss of weight and weakness, are late manifestations of lesions which cause obstruction to the passage of food with or without ulceration and infection. Pain arising from esophageal lesions consists of two types. The first is the result of esophagospasm at or just above a point of obstruction and is referred in a segmental manner to the substernal region, to the back and sometimes to the neck. It is the type of sensation which everyone has experienced from swallowing too large a bolus of food, with temporary lodgment at some point in the esophagus. A reasonably accurate prediction of the location of an esophageal lesion can be made from the level beneath the sternum or in the back to which the pain is referred. The second type of pain is continuous and deep and is felt within the middle of the chest or in the back. This is due to invasion of the periesophageal mediastinal tissues by tumor or to the extension of infection with the production of periesophagitis or mediastinitis.

Roentgenography. Every patient who complains of dysphagia, no matter how insignificant it may seem, should be examined with a contrast medium. Examination of the esophagus while barium is being swallowed frequently leads to enough suspicion to make further investigation by esophagoscopy imperative, if it does not prove the presence of esophageal disease at once. It is important, however, that the physician who refers the patient to the roentgenologist should make it clear that a disorder of the esophagus is suspected. Otherwise, attention is likely to be concentrated on the stomach and duodenum after a cursory inspection of the descent of the barium through the esophagus.

Esophagoscopy. By means of direct visualization of the interior of the esophagus, a definite diagnosis can often be made when

esophageal disease is suspected. This possibility is further enhanced by the fact that bits of tissue from suspicious-looking areas can be removed for histologic examination. An esophagoscopic examination should be advised in every patient in whom the clinical history points to an esophageal lesion, especially if the roentgenographic findings are inconclusive or negative. If this precaution is not observed, the opportunity to establish an early diagnosis, particularly of carcinoma, may often be missed. The performance of esophagoscopy and the use of the esophagoscope for local treatment or as a means of directing the passage of bougies for dilation of a stricture require training, skill and experience.

MEGAESOPHAGUS (ACHALASIA)

Idiopathic dilatation and hypertrophy of the esophagus, the most frequent disorder of this organ after carcinoma, is commonly and erroneously spoken of as cardiospasm because of the false concept that the condition results from muscular spasm at the cardia. The condition, however, is in fact a disease of the esophagus and has nothing to do with the gastric cardia. Furthermore, it is not primarily due to muscle spasm nor is spasm an outstanding characteristic in every instance. It may occur in individuals of any age. It has been observed in infants, but it may not become obvious until old age. In the majority of patients, however, it becomes troublesome in early adult life.

Two types can be recognized by the differences in their clinical manifestations, the roentgen ray findings and the anatomic characteristics as demonstrated at the operating table. In the more common variety, comprising approximately two-thirds of the cases, the esophagus except at the lower end is enormously dilated and hypertrophied. In the distal few centimeters, however, there is a striking narrowing with a diameter often no greater than that of the little finger. In this narrow segment the muscular layer is thin and atrophic, in sharp contrast with the hypertrophy of this layer above.

The roentgen ray examination in patients with dilatation of this type portrays the narrowed lower end of the esophagus and the large dimensions of the major portion of the organ which will often hold a quart or more of liquid (Fig. 20). In addition, when observed under the fluoroscope, the esophagus is found to be atonic with almost complete absence of peristaltic activity. An esophagus

The first suture in the muscle layer is in place but not yet tied. e, Closure of the muscle layer is completed. In situ view of the field of operation before closure of the wound

operation may still be of value for an occasional patient.

Pulsion or true diverticula developing in the lower esophagus are of rare occurrence. They emerge through a weak point in the muscular coats just proximal to the sphincter-like lower mediastinal segment of the esophagus. Thus they lie several centimeters above the level of the diaphragm, a fact which gives rise to the frequently-used designation "epiphrenic diverticulum." Symptoms consist chiefly of dysphagia, regurgitation of previously ingested food, substernal or back pain and sometimes loss of weight and serious interference with nutrition. Their removal is easily and safely accomplished by a one-stage transthoracic operation. The actual details of technique in the handling of the diverticulum itself and the closure of the opening which remains in the esophagus after the removal of the sac are identical

with the technique applied in the treatment of those of the pharyngoesophageal type in the neck.

False Diverticula. Diverticula of the so-called traction variety (Fig. 24) are produced by the pull upon the esophageal wall of a cicatrizing adjacent inflammatory process, usually tuberculous lymphadenitis in the subcarinal region of the mediastinum. They often consist merely in a distortion or sharp angulation of the side of the esophageal wall which becomes adherent to the nearby inflamed lymph nodes. In the typical case, they produce no symptoms and are discovered during routine roentgen ray examination of the esophagus. No treatment is necessary except in the rare patient in whom a calcified lymph node may ultimately ulcerate into both the esophagus and the trachea or a fistulous tract between the two organs. In such

control of the lower segment which is characteristic of this disease. It was Hurst who proposed that megaesophagus results from a lack of the normal coordination between the mouth of the esophagus and the lower segment, leading to a failure of the latter to open at the proper moment after deglutition is initiated. For this phenomenon he proposed the term *achalasia*.

In a large proportion of the patients a favorable response results from dilation of the lower esophagus with the hydrostatic dilator or a mercury bougie. In many instances, a single treatment is followed by striking improvement or actual disappearance of the symptoms, often for long periods. In others, the response is either incomplete or of limited duration and resort must be had to surgical intervention to bring about further relief. The procedure to be employed depends upon the anatomic type of the lesion involved. When an obvious hypertrophy of the distal circular muscle fibers exists, the dysphagia can be relieved by making a longitudinal incision completely through the thickened muscle layer down to, but not into, the mucosa (esophagomyotomy). In the group of patients who have a thin-walled, atrophic segment at the lower end, esophagoplasty consisting of a lengthwise incision through the esophageal wall in the constricted area followed by a circumferential closure of the opening accomplishes the same result.

Permanent relief of dysphagia can be brought about by surgery, but it is not possible to restore the esophagus to a normal condition. Although the degree of distention of the esophagus decreases, often to a striking extent, after the operation, the histologic changes characteristic of the underlying pathologic process remain unchanged.

DIVERTICULA

Diverticula of the esophagus are usually spoken of as being of the pulsion or traction type, according to their supposed etiologic background. Only the former, however, is a true diverticulum. The other is a false, or pseudo, diverticulum, resulting from the traction of an adherent adjacent inflammatory process.

True Diverticulum. Pulsion diverticulum of the esophagus, which consists of a herniation or bulging of mucosa and submucosa through a weakened portion of the muscular coat, occurs either at the pharyngoesophageal junction or in the lower segment of the

thoracic portion of the esophagus just above the diaphragm. Pharyngoesophageal diverticula (Fig. 22) are much the more frequent. The diverticulum arises from the posterior pharyngeal wall just above the cricopharyngeus muscle and, as it enlarges, extends downward behind the esophagus, often veering slightly to the left as it descends. It may assume large proportions over a period of years. The symptoms are characterized by varying degrees of dysphagia, regurgitation of food (often that consumed days previously), the occurrence of peculiar and often embarrassing noises in the neck and throat during deglutition and, ultimately, in the very large ones, serious interference with nutrition, because of the difficulty in swallowing as a result of compression of the esophagus by the overdistended pouch. Elderly patients sometimes aspirate material into the trachea. Cough from tracheal irritation is a frequent symptom.

The ideal surgical treatment is excision of the sac. Under the prophylactic protection of penicillin and streptomycin, and with careful surgical technique, this can be accomplished in one stage with a minimum of inconvenience to the patient (Fig. 23). Under unusual circumstances of poor general condition, or for other reasons, the two-stage

Figure 22 A roentgenogram made after ingestion of barium, showing a large pulsion diverticulum of the pharyngoesophageal junction.

tion ensues, is enhanced by the edema and esophagitis which soon develop. If prompt treatment is not instituted, secondary periesophagitis, mediastinitis and empyema may develop. Early in the management of such a case, it is important to determine from the clinical history or the use of roentgenography the size, shape and density of the foreign body. The roentgenogram will establish the location if the object is radiopaque. A negative finding, however, is not conclusive and must be supplemented by esophagoscopic examination in the hope not only of making the diagnosis but also of removing the object. The majority of foreign bodies can be removed by means of instrumentation through the esophagoscope. In some patients, however, this is best accomplished by pushing the object into the stomach, whence it will probably pass through the remainder of the gastrointestinal tract without difficulty. Esophagotomy is rarely indicated but should be applied without hesitation if difficulties are encountered with the use of other methods.

If the impacted object is known to be a piece of meat, it can usually be dislodged promptly by the administration of a 5 per cent solution of papain which softens and liquefies the bolus so that it will pass on into the stomach.

INFLAMMATORY LESIONS

Chemical Burns with Cicatricial Stenosis. The ingestion of caustic liquids in the form of strong acids or alkalis causes severe chemical burning of the esophagus, often with total destruction of the mucosal layer. This results ultimately in the formation of a stricture as the acute inflammatory reaction subsides and is replaced by cicatrization. The extent of such an injury depends upon the amount of liquid swallowed, its concentration and the rapidity of its passage through the esophagus. Victims vary from those with one or more short areas of involvement, usually at the lower end, to those with complete destruction and cicatricial obliteration of the entire esophagus from the pharynx to the cardia (Fig. 25).

The immediate treatment consists in administering the appropriate antidotal solution and combating the pain, shock and dehydration. During the acute phase of the injury the administration of Meticorten may diminish the degree of swelling and the severity of the inflammatory changes. The usual precautions required for the employment of this drug must be observed.

Gastrostomy may be required in order to maintain nutrition. If the damage is not too severe, ultimate obstruction may be avoided

Figure 25 Roentgenogram showing an extensive chemical burn of the esophagus with involvement of almost the entire length of the organ in a young girl, seventeen years of age, who had swallowed a solution of HCl with suicidal intent (posteroanterior and lateral views).

Figure 24 A, Drawing of a "traction" diverticulum showing funnel-shaped distortion of the wall of the esophagus produced by the pull of adhesions to adjacent inflamed subcarinal lymph nodes (Terracol, J., and Sweet, R. H. *Diseases of the Esophagus*) B, A roentgenogram made after ingestion of barium, showing a traction (false) diverticulum of the esophagus in the midthoracic segment

a patient, a direct exposure of the area through a thoracotomy incision is necessary to make it possible to close the fistula tract.

TRAUMA

Injury to the esophagus by external violence is rare and is almost always associated with serious damage to other viscera. Penetrating wounds produced by the passage of missiles or sharp instruments, on the other

hand, may involve the esophagus without much damage to adjacent structures. In such patients, immediate direct exposure of the injured area may make it possible to deal with the laceration in a satisfactory manner and prevent the prolonged disability which results from fistula formation, with the attendant infection of the neck or mediastinum

In nonmilitary practice, the most frequent source of injury to the esophagus is the result of perforation either with the esophagoscope or, more often, as a result of attempts to pass a bougie. The most frequent site of injury by the esophagoscope is the cervical area. The location of perforations by instrumentation with a bougie is usually just proximal to or actually through the area of constriction which it is intended to dilate. In either case an early operation to suture the damaged area should be considered. The majority of small injuries produced by the esophagoscope, however, heal spontaneously and if the element of infection is minimized by prompt and adequate administration of antibiotics, periesophageal abscesses and severe mediastinitis rarely develop. If such an abscess should occur, however, drainage through the neck or by posterior mediastinotomy is necessary.

Spontaneous rupture of the esophagus sometimes occurs as a complication of violent attacks of vomiting resulting from sudden compression of an overdistended stomach due to external violence such as a fall from a height. The rupture always develops in the lower mediastinal segment and is attended by the sudden development of excruciating pain in the lower portion of the chest with radiation to the back. If the condition is recognized promptly an immediate operation to close the defect is curative. If untreated, however, a mediastinal abscess develops which may perforate into one or both pleural cavities. Surgical drainage then becomes necessary and a prolonged illness ensues, usually complicated by the presence of an esophagopleurocutaneous fistula which may require an additional operation for closure. The mortality rate of this condition is high.

Impaction of a foreign body in the esophagus may result in perforation, either because of ulceration through an area of pressure necrosis or by laceration produced by a sharp edge or point. Manipulative attempts to remove the object are also a frequent source of injury. Impaction of a foreign body may also cause obstruction which, if infec-

with the Plummer-Vinson syndrome are of a precancerous nature. In fact, carcinoma of the upper end of the esophagus occurs much more frequently among women than among men, whereas in the lower esophagus the reverse is true.

The involvement of the esophagus by specific infections, such as tuberculosis, syphilis and actinomycosis, is a rare occurrence in the present day. No distinctive subjective symptoms are observed. The diagnosis can rarely be established without the aid of histologic studies of biopsy or autopsy specimens. The treatment should be directed toward the control of the generalized infection by whatever means may be indicated, including the use of penicillin and streptomycin.

Esophagitis and stricture formation, sometimes severe enough to require surgical intervention, is an occasional complication of scleroderma.

VARICES OF THE ESOPHAGUS

Esophageal varices are the most frequent cause of massive bleeding from the esophagus. They develop in patients with portal hypertension, either from thrombosis of the portal or splenic veins or from cirrhosis of the liver. The diagnosis suggested by the occurrence of copious vomiting of bright blood can usually be confirmed by roentgen ray visualization after the ingestion of barium. This condition has been the subject of much study in an attempt to elaborate a

Injection of the swollen veins, which can be effected through the esophagoscope, has been tried with indifferent success. Certain surgical operations, such as splenectomy, ligation of the splenic artery and interruption of the periesophageal veins, have proved disappointing. A great advance in the management of the condition has been made in recent years by producing a shunt of the portal blood into the systemic venous system, either by anastomosis between the splenic vein (after splenectomy) and the left renal vein or by direct anastomosis between the portal vein and the vena cava (Eck fistula). The success of this procedure arises from the reduction of the pressure within the dilated veins, which in turn diminishes or abolishes their tendency to bleed.

BENIGN TUMORS

Benign tumors of the esophagus occur infrequently, but when they become large,

Figure 27 A roentgenogram made after ingestion of barium, showing the defect produced by a leiomyoma of the esophagus.

they may cause dysphagia severe enough to require surgical intervention. Solid tumors of a benign character are encountered somewhat more frequently than cysts. The diagnosis is usually strongly suggested by the x-ray examination made after ingestion of barium (Fig. 27). In some patients the use of the esophagoscope may be necessary for confirmation. The tumors are usually leiomyomas or fibromas. Lipomas are seen occasionally and cysts, often of a congenital origin, may be observed. Some of the solid tumors hang from a pedicle and can be removed through the esophagoscope by using a snare. Others grow within the wall of the esophagus and their removal requires a direct surgical approach to the region involved.

MALIGNANT TUMORS

Sarcoma of the esophagus is a rare tumor. In the cervical or upper thoracic segments, where striated muscle fibers exist, a rhabdomyosarcoma may occasionally be found. Leiomyosarcomas may develop at any level. A lymphosarcoma of the esophagus may be seen on rare occasions. The symptoms produced by these lesions are not characteristic and the x-ray appearance may not be helpful. A positive diagnosis can be established only by biopsy or examination of the lesion

by bougienage repeated at intervals as required. In order to facilitate the passage of the bougie, the patient should be made to swallow a silk thread as early as possible. In spite of the relative success of treatment by bougienage, many patients finally develop such a tight stricture that either the treatment fails of its accomplishment or perforations result. When it becomes apparent that dilation is either too dangerous or too unrewarding, the patient can be cured permanently by reconstructive surgery to establish a new passageway from the pharynx to the stomach. This may be accomplished by partial esophagectomy with primary intrathoracic esophagogastric anastomosis or, in some instances, by substitution of a segment of jejunum or of the right half of the colon as a by-passing procedure without the removal of the esophagus. Either of these techniques is superior to the use of skin tube substitution because of the tendency of the latter to form strictures and because of the time required to complete them.

Nonspecific Esophagitis and Ulceration. Localized areas of inflammation not due to any recognizable mechanical or chemical trauma occur actually more frequently than was formerly supposed. The etiologic factor cannot always be determined. Esophagitis may exist as a complication of acute pharyngitis. It has been known also to result from agranulocytosis following the ingestion of sulfonamide drugs (Fig 26). It may be found at any level in the esophagus but it is most frequently encountered in the lower end, where it is usually associated with the presence of a short esophagus and thoracic segment of stomach. It is unusual for esophagitis to occur as a complication of an esophageal hiatus hernia of the acquired type.

Ulceration, sometimes considered of the peptic variety, is a frequent occurrence in the esophagitis which develops near the cardia. These ulcerations may develop in anomalous gastric mucous membrane which extends upward from the cardia into the esophagus, but they frequently involve the mucosa of the esophagus itself as well. The symptoms are pain, often of a dull gnawing variety referred to the substernal or epigastric area, mild to severe degrees of dysphagia, the sensation described as "heartburn" and sometimes hematemesis. Treatment is dietary and medicinal at first. If the dysphagia becomes a problem, one or more dilations may be required. Some cases, however, result ultimately in the formation of a tight stricture caused by the circumferential contraction of the scar tissue which de-

velops in the ulcer bed as healing of the ulcerated area progresses. Attempts to overcome this difficulty by the passage of bougies, if not disastrous because of perforation, are ineffectual because of the prompt re-formation and contraction of scar tissue. Under these circumstances a resection becomes necessary. An occasional indication for resection also is the occurrence of severe bleeding.

An important form of chronic esophagitis seen almost exclusively in women beyond middle age is a part of the clinical condition known as the *Plummer-Vinson syndrome*. Patients who exhibit this picture experience dysphagia especially for solid foods, which become lodged at the mouth of the esophagus, to which the stenotic process is confined. Ease of fatigue which accompanies the condition is due to a sideropenic (iron deficiency) anemia of long duration. The mucosa of the mouth, pharynx and tongue may be pale, smooth and glistening. The latter may show fissures and superficial erosion with a tendency to leukoplakia. The skin of the vulva and anus may present a similar appearance. There is usually achlorhydria.

There is strong clinical evidence to suggest that the mucosal changes in the retrocricoid segment of the esophagus in patients

Figure 26 A roentgenogram made after ingestion of barium in a patient with agranulocytic esophagitis with resulting cicatricial atresia of the esophagus. The agranulocytosis was caused by ingestion of a sulfonamide.

pitiable that the possible benefits of surgical treatment should be offered to all if there is a reasonable prospect of removing the growth and re-establishing the continuity of the alimentary canal by anastomosis. The operation is planned to bring about a cure in the relatively few favorable cases, but, of equal importance, it should provide the maximum relief of discomfort in the larger group of patients whose disease is beyond the hope of cure. X-ray treatment is of limited value as a method of palliation and has produced few long survivals in patients with proved carcinoma of the esophagus.

The technical problem in the surgical management of carcinoma of the esophagus varies somewhat from one level to another. It is now possible to resect the growth and re-establish continuity so that the patient can eat in a normal manner in every case in which the growth is resectable.

In the cervical segment of the esophagus, the growth can be removed and a flap of skin turned in from the neck so as to make a skin-lined tubular substitute for the excised portion. The operation is performed in two stages. By this means, complete restoration of function can be brought about, but it is applicable only in early, favorable cases, because of the fact that not a large enough number of regional lymph nodes can be excised.

The older Torek procedure, which permitted only relatively local resection of the growth and made no provision for excision of many of the regional lymph nodes, resulted in a very small number of long survivals. Furthermore, because it left the patient with a proximal esophagostomy in the neck and a gastrostomy for feeding purposes, it provided a most inadequate degree of palliation even if the surgeon succeeded ultimately in constructing a substitute esophagus, either by a skin plastic procedure or by the interposition of a segment of the jejunum or the colon. This operation is therefore no longer used.

As a result of recent advances in surgery of the esophagus, radical resection of the diseased segment and wide excision of many of the regional lymph nodes are possible, especially in the lower region of the thorax. At the same time a restoration of the continuity of the alimentary canal can be brought about by esophagogastric anastomosis. The exact details of the technique must be altered from case to case, depending on the location of the growth. The operation

is performed through a left thoracotomy incision and involves opening the abdomen by incising the diaphragm in order to gain access to the stomach, which must be pulled up to meet the proximal segment of the esophagus for the performance of the anastomosis after the growth has been removed. Depending upon the location of the tumor and the level at which the esophagus must be severed, the anastomosis is made either just below or just above the aortic arch. In the rare patient in whom the tumor involves the superior mediastinal segment of the esophagus, an additional cervical incision must be made and the stomach brought up through the chest and into the neck, because of the necessity for cutting across the esophagus in the cervical segment (Figs. 29 and 30). An alternative technique, the use of which is now being explored in this group of cases, is the substitution of a long segment of the colon (Fig. 31).

Carcinoma of the lower esophagus and cardiac end of the stomach is treated in exactly the same manner as that arising at a higher level in the thorax, with the exception that more of the stomach must be resected with the excised segment of esophagus. The esophagogastric anastomosis in these patients is made at a relatively low level in the chest.

So far as late results are concerned, there is already enough knowledge available from the experiences of patients whose operations

Figure 29. A diagram showing a step in resection of the esophagus for carcinoma of the mid-thoracic portion, with high intrathoracic (supra-aortic arch) anastomosis.

after its removal. In the case of lymphomatous tumors, a favorable temporary response may result from x-ray treatment.

Carcinoma of the esophagus comprises the overwhelming majority of malignant neoplasms of that organ. In fact, the most frequent lesion of any kind in the esophagus is carcinoma. It may develop at any level within the esophagus, but the most frequent site is in the middle half. In the lower end, a certain amount of confusion results from the fact that approximately four out of five growths which invade the cardia arise in the stomach, are adenocarcinomatous and are not actually esophageal in origin, although the lower segment of the esophagus is usually invaded. Carcinoma arising primarily in the esophagus itself is typically epidermoid histologically, but the degree of malignancy of these tumors is of a high order. In over 70 per cent of the patients in whom resection of the growth can be performed, metastases to the regional lymph nodes are already present. Extension of the growth in the wall of the esophagus is often wide and involvement of adjacent organs by direct invasion frequently occurs relatively early in the progression of the disease. All hope of cure therefore rests on the establishment of an early diagnosis and the prompt resort to surgical extirpation.

The onset of the disease is insidious and its development is well advanced before the patient is aware of any abnormality. The first symptom is dysphagia, often intermittent, depending upon the physical properties of the food ingested. As the condition advances, the encroachment upon the lumen of the esophagus increases and in a relatively short time the patient finds that only soft foods will pass down and finally nothing but liquids. In the late phase of the disease, pain, which is of two types, may be experienced. The first is that which results from local distention or muscle contraction just above the level of the growth and is the result of esophagospasm. It is referred in a segmental manner to the substernal region, with radiation to the back and sometimes into the neck. It may be high or low, depending upon the level of the tumor in a given subject. The second type of pain is a steady, boring discomfort felt deep within the chest and in the back. This is the result of the direct invasion of surrounding tissues by tumor growth or the development of periesophagitis and mediastinitis from an ulcerating infected lesion.

Figure 28 A roentgenogram made after ingestion of barium, showing an annular filling defect, characteristic of carcinoma of the esophagus.

In the majority of patients, a roentgenogram made after the ingestion of barium will demonstrate the characteristic irregular filling defect, usually annular in extent, involving the esophagus at whatever level the tumor may be located (Fig 28). If the growth happens to be an early one, the x-ray examination may not prove to be conclusive. In any such patient, if the history suggests the probability of an esophageal lesion, it is mandatory to perform esophagoscopy. By means of the endoscopic examination, a diagnosis can usually be made with certainty by obtaining tissue for biopsy. It should be pointed out, however, that unless the grasp of the forceps is deep, it may happen that only surrounding inflammatory tissue may be obtained for histologic study. In such an instance, the procedure should be repeated or resort made to surgical exploration.

Recent experience has shown that cytologic studies of material obtained from the esophageal lumen by washing with saline solution result in a high percentage of positive results. In many instances, the employment of this method eliminates the need for esophagoscopy to establish the diagnosis. A negative result, however, must not be assumed to indicate the absence of this disease.

The ultimate fate of patients with carcinoma of the esophagus is so hopeless and their plight during the last days of their lives

Figure 30. A roentgenogram made postoperatively after ingestion of barium, showing high intra-thoracic esophagogastric anastomosis with the fundus of the stomach in the apex of the chest

were performed five or more years before the observations were made to demonstrate that there is hope for cure in an appreciable number of patients with carcinoma of the esophagus

In an experience of over eighteen years, it has been demonstrated that, given favorable cases with no evidence of lymph node metastases, at least 34 per cent of the patients who have had a resection of the lower end of the esophagus for carcinoma and 23 per cent of those operated upon for a carcinoma of the midthoracic segment have survived five or more years after operation.

There is reason to believe, therefore, that the long-term results following resection and primary anastomosis in patients with carcinoma of the esophagus are as good as those for resection of any other portion of the alimentary canal, with the possible exception of the rectum.

As with carcinoma elsewhere, a large number of the patients who have had resection performed will ultimately succumb to the effects of recurrent or metastatic disease. In this group the operation of resection and intra-thoracic esophagogastric anastomosis is the best method of palliation available at the present time, because in the majority of these patients a recurrence of the growth does not develop at the site of anas-

Figure 31. Diagram illustrating the employment of the right colon to supplant the esophagus. Arrow shows the direction of peristalsis in the transplanted bowel.

tomosis. The result is that the patient continues to eat in a normal fashion as long as he survives.

With those patients whose growth cannot be removed, the interposition of a segment of the colon between the cervical esophagus or the pharynx and the stomach, followed by intensive irradiation of the tumor, appears to be a satisfactory means of amelioration. Further experience with this method is required before final evaluation of its efficacy from the standpoint of survival can be made.

that a greater predisposition to gastric ulcer exists in these Andean natives. In the high altitudes, vascular and hematic factors, as well as chronic occupational stress, may play a most important role in the etiopathology of gastric ulcer.

The stomal ulcer is generally rated as occurring in 16 to 34 per cent of patients following gastroenterostomy, while following subtotal resection it has a lower incidence, usually rated as around 6 per cent. The incidence of perforation in cases of peptic ulcer is estimated as from 3 to 8 per cent and of recurrent acute perforations as 1 to 1.5 per cent. The incidence of hemorrhage is much higher, varying according to different observers between 5 and 25 per cent. The risk of later hemorrhages is greater in patients who have had more than one hemorrhage. The belief that a greater incidence of ulcer activity occurs in the spring and fall seasons with an apparent high incidence of hemorrhage from October through January, has become a tradition not easily proved by reported statistics. It is probable that many gastric ulcers are undiagnosed during life because of the bizarre symptoms which they present.

Anatomy. Knowledge of the anatomy, blood supply and innervation of the stomach and duodenum is fundamental to an understanding of the basic features of the disease. Such an understanding is also important in

evaluating the various methods which have been employed to treat peptic ulcer.

The stomach lies between the cardiac and pyloric sphincters and includes the fundus, the corpus and the antrum. The lower part of the antrum is loosely termed the pyloric or prepyloric region. The arteries to the stomach are plentiful. This excellent blood supply has the advantage that healing is prompt after operation but, at the same time, the disadvantage that bleeding is difficult to control. Bentley and Barlow demonstrated that while in the rest of the stomach the mucosal arteries come from a rich submucosal plexus, along the lesser curvature they rise directly from the long, slender branches of the right and left gastric arteries which pierce the muscularis directly. Thus apparently more precarious arrangement of the vascular supply may explain the predisposition of the magenstrasse to develop gastric ulcer. The presence of arterial-venous anastomosis in the stomach was demonstrated by Barlow, Bentley and Walter in 1951 and was confirmed by Sherman and Neumann in 1954 (Fig. 32). The veins and the lymphatics tend to follow the arteries.

The nerves include the vagi, a left anterior and a right posterior, which stimulate gastric secretion and the sympathetic fibers which probably inhibit gastric secretion.

The most important cells in the stomach are the parietal cells which are especially

The Stomach

Peptic Ulcer and Benign Gastric Lesions

By CLIFFORD J. BARBORKA, M.D.

CLIFFORD JOSEPH BARBORKA attended Simpson College in Iowa, graduated from the University of Chicago and received his degree in medicine from Rush Medical College. His interest in gastroenterology was stimulated during his internship and developed during his years as a staff physician at the Mayo Clinic. Doctor Barborka, Director of the Gastrointestinal Clinic at Northwestern University Medical School, is a leader in his specialty and is well qualified by his wide experience and flexibility in methods of therapy to present the physician's views upon peptic ulcer.

PEPTIC ULCER

Peptic ulcer is a localized loss of the mucous membrane with secondary involvement of the muscularis. The identity of peptic ulcer is recognized in four areas of the upper gastrointestinal tract (1) in the lower esophagus, where it occurs rarely and is ascribed to regurgitation of the acid contents of the stomach, (2) in any part of the stomach itself, where it must be differentiated from an ulcerating carcinoma, (3) in the first or second portion of the duodenum, and (4) in the jejunum at the stoma of an operative anastomosis.

Incidence. The incidence of ulcer in the United States is difficult to determine with any degree of precision, since there is a marked discrepancy in statistics from various sources and for various reasons. In autopsy studies, the results of which often vary greatly from studies in living groups, it is thought that scars of previous ulcers, particularly in the duodenum, may have been overlooked or may not be present at all when an ulcer has completely healed. In studies of living individuals, age and sex variations distort the true perspective in ulcer incidence. However, statistics from all these sources indicate that between 8 and 10 per cent of our population will be afflicted with this disease within their lifetimes. Of patients seeking relief for diges-

tive symptoms, about 15 to 20 per cent are found to have an ulcer. This means that a most important productive age group of the population is struck by this disease and the economic repercussions are extremely important.

The annual mortality from peptic ulcer is 10,000 in the United States. Persons of any age may be affected, although it is most common in those in the younger and middle years. Males are affected four times as often as females. The incidence of duodenal ulcer is much higher than that of ulcer in other locations. Its incidence, as compared to that of gastric ulcer, is estimated as three to ten or more times as great. There is an interesting exception to this estimation. Garido Klinge and Luis Pena, observing patients in the Peruvian Andes, made a most provocative report on gastroduodenal ulcer in respect to high altitudes. The general incidence of gastroduodenal ulcer in their group of 17,500 insured laborers, chiefly miners, born and living in the Peruvian Andes at an altitude of 10,000 to 16,000 feet above sea level, is 0.4 per cent. The relation of gastric to duodenal ulcer is astounding, the proportion being 20.6 to 1 per cent. The greatest incidence of gastric ulcer occurs in persons between twenty-one and thirty years of age. Particularly astonishing is that hemorrhage occurred in 68 per cent of cases. It appears

nonreciprocal permeability which allows only water with hydrogen and chloride ions to pass through it into the lumen of the gland. Bicarbonate is returned to the blood.

Davenport has shown that carbonic anhydrase, an enzyme which catalyzes the reaction of carbon dioxide and water to form carbonic acid and its ionic breakdown, is present in high concentration in the parietal cells. The carbonic anhydrase serves primarily to maintain ionic and isotonic equilibrium within the parietal cells. It participates in the reverse chloride shift wherein chloride is secreted in exchange for bicarbonate. It appears that carbonic anhydrase furnishes one source of hydrogen ions for hydrochloric acid. This is supported by the observation that the administration of carbonic anhydrase inhibitors such as acetazolamide may markedly inhibit the production of hydrochloric acid. It has been postulated by Conway and others that the hydrogen is concentrated by a series of steps employing a so-called redox cycle (Fig. 34).

Pure parietal secretion contains per liter 166 mEq. of chloride, 159 of hydrogen ion and 7 of potassium ion. This solution is iso-

osmotic with blood. Gastric juice does not reach this concentration because nonparietal secretion neutralizes and dilutes the parietal secretion. High concentration of acids has been observed, up to 110 clinical units (a clinical unit being equal to 1 mEq. per liter), and under strong stimulation the acid concentration of gastric juice may reach as high as 150 mEq. per liter.

Pepsin. Pepsinogen, a protein, is formed by the chief cells and is converted to pepsin in an acid medium (below pH 6). The optimum pH for the proteolytic activity of pepsin is about 2. Stimulation of the vagus nerve produces an increase in secretion of gastric juice which contains mucus and is high in peptic activity. Stimulation with histamine, on the other hand, yields a highly acid secretion which is low in peptic activity and practically mucus free.

Mucus. Gastric mucus is secreted by the surface epithelial cells, by the chief cells of the neck and fundic glands, by the pyloric gland cells and by the cardiac gland cells. There are two components of mucus in the fundus and body of the stomach. The first is a layer of viscous mucus which covers

REDOX CONCEPT OF HYDROCHLORIC ACID SECRETION (CONWAY)

Figure 34 Schematic diagram of the redox concept of gastric secretion, according to Conway (Texter, E. C., Jr., and Barborka, C. J. *Gastroenterology*, vol 28)

Figure 33 Cross section of a gastric gland (Barborka, C. J., et al. Quart. Bull. Northwestern Univ. Med. School, vol. 28)

plentiful in the corpus. There are essentially no parietal cells in the antrum. The parietal cells secrete hydrochloric acid. The chief cells secrete pepsin. In the proximal duodenum there is a special layer of cells, the so-called Brunner's glands, which secrete mucin that may protect the duodenum against peptic digestion.

Physiology. Knowledge of the basic physiologic processes of gastric secretion and motility is as important as (if not more important than) knowledge of the anatomic features. Peptic ulcer results from an alteration in normal physiology. An understanding of the normal physiology is essential to an understanding of the abnormal. The physiology of the stomach and the duodenum is of great importance in studying and understanding the different affections of this region, not only peptic ulcer but the others as well.

Gastric secretion. An imbalance between the eroding or destructive factors in gastric secretion and the defense factors is considered important in the development of an ulcer. This balance may be disturbed in several ways. There can be an increase in the quantity or duration of the secretion of the hydrochloric acid-pepsin combination; there can be a decrease in the secretion of the buffering fluids which neutralize and inactivate the hydrochloric acid-pepsin com-

bination and, lastly, there can be a decrease in the resistance of the local tissues to the action of the erosive hydrochloric acid-pepsin. In order to understand the factors underlying this imbalance, it is essential to know what the normal mechanism of gastric secretion is.

Two portions of the stomach are concerned with gastric secretion. The proximal two-thirds of the stomach contains millions of tubular glands whose function is to produce the active digestive elements of gastric juice, namely, pepsin and hydrochloric acid. Pepsin, the digestive enzyme, is formed by the chief cells which are located in the body of the gland, while hydrochloric acid is formed by the parietal cells. The surface epithelial cells secrete mucus. The distal third of the stomach contains the pyloric glands, whose chief function is the formation of mucus (Fig. 33).

COMPONENTS OF GASTRIC SECRETION Hydrochloric acid. The complete details of the mechanism of secretion of hydrochloric acid are not entirely clear. It is known that the main constituents—water, carbon dioxide and the chlorides—are derived from the blood. It is probable that water furnishes the source of the hydrogen of hydrochloric acid. Hollander has proposed the "membrane hydrolysis" theory, which postulates that the canalicular wall has a selective,

partially digested protein act as gastric juice secretagogues when they are within the bowel. This hormone is not believed to be enterogastrone, an inhibitory hormone.

4. *Hypothalamic-pituitary-adrenal phase.* During the past five or six years there has been a growing body of evidence suggesting that gastric secretory activity may be influenced by endocrine as well as neurogenic factors. Recent studies suggest that stress may be mediated to the stomach not only by the vagus nerve, but by a purely hormonal mechanism transmitted through the hypothalamic-pituitary-adrenal pathway, independent of the vagus nerve or gastric antrum. Thus, the gastric and peptic glands may be integrated into the general endocrine system.

The hypothalamus has been described by Cannon as the seat of primitive human emotions. An intact hypothalamus is essential for the transmission of emotions to the pituitary. Leonardo da Vinci, many centuries ago, located the soul in the vicinity of the hypothalamus. A number of systemic stress factors, such as muscular exertion, fatigue and temperature changes, as well as chronic emotional stress, that is, rage, fear, anxiety and frustration, may induce the hypothalamus to secrete a humoral substance which then stimulates the pituitary gland to secrete corticotropin (adrenocorticotrophic hormone) as part of the general adaptation syndrome. Corticotropin, in turn, activates the adrenal cortex to release a number of steroid hormones including cortisone and cortisone-like compounds.

Gastrointestinal ulceration with hemorrhage or perforation is an integral part of the alarm reaction. Repeated administration of corticotropin stimulates certain forms of stress. Both the corticotropin and the stress may produce an increase in the output of adrenal corticoids which can be measured in the blood and urine.

The adrenal cortex may have a dual role in the gastric responses to stress according to the "permissive" concept and the "conditioned" theory of hormonal activity. The adrenal may function as an agent which "permits" a gastric response to occur, without whose presence the response could not occur. The second role casts the adrenal in a more direct relationship between the levels of adrenal cortical hormone attained and the extent of the gastric responses. Excess adrenal hormone may sensitize the stomach to respond more readily or stress itself may condition the stomach to respond to adrenal

hormone. It would therefore appear that the adrenal steroids may sensitize the stomach to ulcerogenic influences or to other factors yet to be determined, or that the stress itself may cause the stomach to respond abnormally to the adrenal hormone.

Present studies suggest that there are two routes by which stress may be relayed from the hypothalamus to the stomach: (1) a neurogenic pathway involving the cerebral cortex, the anterior hypothalamus and the vagus nerve and (2) a hormonal mechanism mediated through the posterior hypothalamus, the pituitary gland and the adrenal cortex.

a. *Neurogenic pathway.* The neurogenic pathway is by way of the anterior hypothalamus to the vagal centers and the vagus nerve. Direct electrical stimulation of the anterior hypothalamus in animals produces a prompt but unsustained increase in gastric secretion of hydrochloric acid in thirty to sixty minutes, which is abolished by vagotomy. Insulin hyperglycemia also induces prompt gastric hypersecretion in animals and man, attributed to anterior hypothalamic and vagal stimulation.

b. *Hormonal pathway.* A second hormonal phase of gastric secretion mediated through the adrenal cortex to the stomach by way of the hypothalamus and pituitary gland was postulated in 1950 by the observations in man of an increase in gastric hydrochloric acid and pepsin secretion during prolonged corticotrophic hormone stimulation unaffected by vagotomy but requiring an intact adrenal gland. It was suggested that chronic emotional and physical stress might be transmitted to the stomach by a hormonal pathway through the hypothalamic-pituitary-adrenal mechanism independently of the vagus nerve and gastric antrum and that acute or chronic peptic ulcer might be induced in man through this purely hormonal mechanism.

Porter and his associates have shown in monkeys that electrical stimulation of the posterior hypothalamus produced a delayed increase in gastric acidity after two and one-half to three hours, which was abolished by adrenalectomy but not by vagotomy or low cervical cord section. Insulin hypoglycemia also induced a delayed gastric response mediated through the posterior hypothalamus and pituitary-adrenal axis which was abolished by adrenalectomy but not by vagotomy.

A similar delayed gastric acid response to insulin hypoglycemia has been demonstrated in man by Shay and Sun, who observed that

the inner wall of the gastric cavity. The second is a layer of tall columnar cells immediately beneath this sheet of mucus, together with low columnar and cuboidal cells which line the crypts of the gastric glands. Several components have been isolated from gastric mucus, including two types of mucopolysaccharides. Gastric mucosa exists in two physical forms, dissolved mucus and visible mucus. Its function is to coat the mucosa of the stomach, protecting it from erosion. It also inhibits pepsin and neutralizes hydrochloric acid.

STIMULATION OF GASTRIC ACID SECRETION. Gastric acid secretion is stimulated by the following factors

1. *Cephalic (nervous or psychic) phase by action of the vagi.* This usually acts early in the course of a meal, occurring even at the sight, taste, smell or thought of food. Hypoglycemia sufficient to reduce the blood sugar level to below 50 mg per 100 cc or to produce definite symptoms of hypoglycemia acts upon the vagal centers, producing an increased secretion of gastric acid. This action is the basis of the so-called insulin or Hollander test for vagal function. If the test shows no increase in free hydrochloric acid secretion after administration of sufficient insulin to fulfill the requirements listed above, vagotomy has been complete.

Vagotomy eliminates the secretory response of the stomach to sham feeding as shown by Pavlov in 1910. In 1947 Harkins showed that sectioning of the vagus nerves to the stomach in the Shay rat (when the pylorus was ligated in the fasting rat, an average of twenty-two gastric ulcers per rat developed within twenty-four hours) prevents the formation of gastric ulcers. Harkins and Hooker in 1947 demonstrated that sectioning of the vagus nerves to the stomach in the Mann-Williamson dog markedly lowers the incidence of marginal ulcer formation. In 1950 Dragstedt and his colleagues demonstrated that sectioning of the vagi to an isolated total stomach pouch or to a Pavlov pouch causes a marked reduction in acid secretion from that pouch. In 1952 Storer and his colleagues showed that the action of the vagi is not a simple one. They demonstrated that cutting the vagi to the main stomach causes an increase in the acid output of a Heidenhain pouch, possibly because of secondary stimulation of the hormonal phase. In 1953 Sauvage and his associates revealed that sectioning of the vagus nerves to a stomach pouch decreases the incidence of stomal peptic ulceration in the

connecting jejunal loop. In 1953 Movius and French showed that stimulation of the anterior hypothalamus produces a prompt rise in the acid secretion of the stomach of monkeys. This response is believed to travel over the vagi, is blocked by vagotomy but not by adrenalectomy and is related to the acute stress ulcer.

2. *Antral (gastric or hormonal) phase.* This is by stimulation of the antrum to produce gastrin which travels by the blood stream, acting as a hormone to stimulate the parietal cells of the corpus and the fundus to secrete, in turn, more gastric acid. There is some evidence that the cephalic phase everts its full effect in the presence of an intact antrum and vice versa, indicating some interdependence of the two stimulating mechanisms. The hormone, gastrin, is an internal secretion of the antral mucous membrane, which contains no parietal cells and acts on the rest of the stomach which secretes no gastrin.

The following points demonstrate the importance of the antrum

In 1906 Edkins of England showed that antral extract injected intravenously caused an increase in acid secretion. The hard-learned clinical fact, that if the excluded antrum is left in place after a partial gastric resection marginal ulcer is more apt to occur, was demonstrated by physiologists and surgeons in the following manners

In 1950 Dragstedt and his colleagues demonstrated the rather fundamental observation that when the antrum is in contact with intestinal contents it stimulates the secretion of hydrochloric acid from Pavlov or total stomach pouches in dogs. When the antrum is isolated, excised or transplanted subcutaneously, it does not act in this stimulatory manner.

In 1952 Oberhelman and his group placed foods and other chemicals in the isolated antrum of dogs and found that it stimulated acid production of Heidenhain pouches. In 1954 Dragstedt and his coworkers showed that physical stimuli, including distention, to the antrum attached to the colon of dogs caused an increase in the acid secretion of Heidenhain pouches.

3. *Intestinal phase.* A hormone similar to but less powerful than gastrin may be secreted by the intestinal mucous membrane when in contact with food. The secretagogues which produce gastric secretion when they are in the stomach also stimulate gastric secretion when they are in the intestine. Substances such as soaps, fatty acid and

ments of the empty stomach give rise to the sensation termed "hunger pangs." These hunger pangs are peristaltic waves which start in the upper stomach region and pass down through the duodenum.

The motor activities of the stomach during digestion can be divided into two types, gastric peristalsis and changes in muscle tone. Gastric peristalsis consists of regular periodic contractions which segment off the distal end of the stomach and carry the portion of the gastric contents through the pyloric sphincter and into the small bowel. In addition to these gross movements, smaller changes, called "tone" changes, have been observed within the stomach. These consist of a gradual shortening of the muscle fibers of the stomach as the volume of gastric contents decreases.

The functions of the stomach during digestion include the reception of the meal, mixing of the contents of the stomach and assuring passage of the gastric chyme into the small bowel. This is a highly coordinated function which has been carefully studied by Quigley and his coworkers. He has observed that the distal portion of the stomach, the pylorus, and the first portion of the duodenum behave as a coordinated segment and he has termed this the "antral pump." It is his opinion that the pyloric sphincter's chief function is to prevent regurgitation of the duodenal contents into the stomach.

Several mechanisms operate to prevent any great increase in intragastric pressure when food enters the stomach. Initially, there is a relaxation of the walls of the stomach and a concomitant inhibition of motor activity. The major portion of the food is held in the reservoir, or upper portion of the stomach, and at periodic intervals portions of the mass are moved down into the antral pump region. The major stimulus for evacuation of the stomach is the size of the meal. Therefore, a large meal leaves the stomach more rapidly than a small meal and for this reason frequent small feedings are advised for patients who have peptic ulcer. The rate of gastric emptying is also regulated by factors acting within the duodenum. It can be observed fluoroscopically that in some patients an initial bolus is passed into the duodenum and then there is no further gastric emptying. An inhibitory reaction takes place within the stomach, suppressing peristaltic activity. The exact nature of this duodenal inhibitory regulation is not understood. In other patients, once emptying is

initiated it is continued until the stomach is emptied of its contents.

Etiology. Peptic ulcers, which represent a localized loss of the mucosal lining tissue in the areas of the gastrointestinal tract bathed by gastric juice, may be the result of multiple etiologic factors. As we all know, the underlying cause of ulcer is still unknown. The two associative causative factors, hydrochloric acid secretion and changes in motility, are as yet the only two targets for practical treatment, although tissue resistance and circulatory changes are also recognized as intermediate factors between the constitutional factor and the culminating production of ulcers. The studies of stress ulcers have been of great interest. The postulate that acid secretion is augmented by increasing circulating adrenal cortical hormones has been widely discussed. The fact that similar ulcers appear in the adrenalectomized animal suggests the possibility that ulcer occurs in the shock phase of the alarm reaction and that its mediation is by some unknown mechanism. Of interest is the fact that increased acid production resulting from corticoid therapy is not blocked by vagotomy, suggesting that the cerebral vagal and the pituitary-adrenal pathways bear two distinct influences on the production of ulcer. With limitations in our knowledge of the exact underlying factor and of its influence on secretion of hydrochloric acid, motility and tissue resistance, we are forced at present to work backward from the suppression of acid and decrease in motility as effective therapeutic measures, instead of forward to such measures from a clearly outlined etiology.

Eroding factors. Erosion takes place both by chemical irritation and as the result of mechanical factors. Hydrochloric acid is necessary for the production and maintenance of a peptic ulcer. Pepsin is likewise important in the development of an ulcer. Gastric secretion tends to be higher than normal in duodenal ulcer patients, but slightly lower than normal in gastric ulcer patients.

Inadequate neutralization of the hydrochloric acid formed by the parietal cells probably plays a role in the development of an ulcer. Normally, the surface or mucous cells of the stomach secrete alkaline mucus which tends to neutralize the acid produced by the stomach. It has been suggested that this mucous barrier is inadequate in ulcer patients.

the late gastric response to the stress effect of insulin hypoglycemia was abolished by total adrenalectomy.

5. *Pancreatic phase.* The pancreas plays a double role in the etiology of peptic ulcer. The first depends upon the fact that exclusion of the external secretion of the organ increases the tendency to ulceration of the duodenum. This observation is the basis of production of the Mann-Williamson experimental ulcer in dogs. The reason for the importance of the internal secretions of the pancreas in gastric secretion is much more complex. Basic studies on the role of the pancreas indicate that its external secretion may prevent marginal ulcers and its internal secretions may be a factor in (1) the acute ulcer (Curling's ulcer, stress ulcer, posterior hypothalamus-stimulated ulcer) or (2) the acute ulcer (Cushing's ulcer, anterior hypothalamus stimulated ulcer), and possibly (3) the intractable ulcer (ulcer diathesis, Strom-Zollinger-Ellison ulcer).

INHIBITION OF GASTRIC ACID SECRETION
Gastric acid secretion is inhibited by the following factors.

1. *Nervous factor.* The action of the sympathetic fibers either may affect the stomach directly or hold the vagal stimuli in check. This was shown by Cushing in 1932.

2. *Antral acid inhibition.* It is believed that when excess acid strikes the antrum, it acts as a signal to the parietal cells to slow down in the production of acid. It is of interest that one organ, namely, the antrum, can be active in both stimulating and inhibiting the production of acid secretion.

3. *Duodenal acid inhibition.* This is a postulated mechanism similar to antral inhibition except that the excess acid acts upon the duodenum rather than on the antrum to cause the production of acid. Enterogastrone, a possible inhibitory hormone produced by the duodenum, may be the factor in duodenal acid inhibition.

4. *Enterogastrone.* This material prepared from the first six to eight feet of fresh hog intestine is a colorless product easily soluble in water. Twenty-five mg. of it will suppress histamine-induced gastric secretion in the total pouch dog. In 1946, Greenwood and his associates reported that only 25 per cent of eight Mann-Williamson dogs injected with purified enterogastrone daily for one year developed ulcer, whereas 100 per cent of ten such dogs given hog muscle extract injections as controls developed ulcer. Preliminary clinical trial by these authors is suggestive of benefit, but the hormone is not

commonly accepted as being of clinical benefit at present.

Gastric secretion as well as gastrointestinal motility may be inhibited by nervous impulses mediated by way of the sympathetic nerves. Inhibition of secretion of hydrochloric acid is also observed after administration of fats or sugars when they are present in sufficient concentration. This is a result of the action of fats and sugars upon the intestinal mucosa, with the production of the hormone enterogastrone. This natural inhibitory mechanism is made use of in treating ulcer patients. Liberal amounts of fat, usually in the form of cream, are included in such diets. This fat stimulates the release of enterogastrone, which inhibits hydrochloric acid secretion and also delays gastric emptying.

REGULATOR OF GASTRIC ACIDITY. The formation of gastric acid is regulated by the factors discussed above, both those which enhance secretion and those which inhibit it. The acidity of the gastric contents is also related to the rate of removal of parietal secretion by emptying of the stomach, the ingestion of food or antacids, the amount of nonparietal or mucous secretion and the amount of secretion extrinsic to the stomach. The last factor includes swallowed saliva, regurgitated intestinal contents and alkaline bile. The amount of acid secretion at the time of a meal depends on both mechanical and chemical factors concerned with that meal and also with the enthusiasm with which the person ingests the meal. It is thought that all patients with free acid form parietal secretion at about the same concentration (approximately 159 clinical units). However, during the course of a meal the level of acidity seldom reaches higher than 50 clinical units, because of the addition of nonparietal secretion and the neutralizing capacity of the ingested food.

Duodenal secretion. The duodenum is supplied with Brunner's glands which resemble histologically the pyloric glands of the distal stomach. The secretion from these glands is a thin, alkaline mucous one which is capable of neutralizing a significant amount of gastric hydrochloric acid. The stimulus for its production is the presence of acid in the duodenum. The vagus nerves stimulate activity of the Brunner's glands while the sympathetic nerves have an opposite effect.

Gastroduodenal motor activity. Motor activity can be observed both when the stomach is empty and when it is full. The move-

Certain personality factors and traits are found in association with peptic ulcer. The ulcer patient is frequently a tense, anxious, driving, active individual.

Pathogenesis. The available evidence indicates that peptic ulcers of the stomach or duodenum have their origin in the acute ulcer. The acute ulcer, or an erosion, goes on to form a chronic ulcer unless the balance between the eroding and the defense mechanisms is restored. The study of experimental ulcers has demonstrated that two factors are common to all of these ulcers. These consist of engorgement of the mucosa and necrosis.

Alterations in the secretory and motor functions of the stomach are equally important. Hypersecretion is present with most duodenal ulcers. Wolf and Wolff have observed that hypersecretion is accompanied by hypermotility and engorgement of the mucosa. All of these act to render the mucosa less resistant to trauma and subsequent ulceration.

Pathology. Acute ulcers. Acute ulcers are superficially located and are frequently multiple. They often follow infections, intracranial disease, neurologic trauma or forms of stress. Most of these ulcers heal, but a few become clinically manifest by the development of bleeding or perforation. Some may ultimately form chronic ulcers.

Chronic ulcers. Chronic ulcers account for the majority of peptic ulcers which cause symptoms. They may be located in the distal esophagus, in the stomach or duodenum, in the small bowel following gastroenterostomy or in a Meckel's diverticulum when heterotopic gastric mucosa is present (Fig. 35). Esophageal ulceration is rare as a primary entity but is frequently found in association with hiatus hernia. Esophageal ulcers account for 4 per cent of peptic ulcer in autopsy subjects.

Gastric ulcers occur with greatest frequency on the lesser curvature side of the stomach, 85 per cent of gastric ulcers being in this region. Sixty per cent of gastric ulcers are within 6 cm. proximal to the pyloroduodenal junction. The pyloric channel is the site of 12 per cent of gastric ulcers. The cardia is less frequently involved and the greater curvature only on a rare occasion.

Ninety-five per cent of duodenal ulcers are within the first 3 cm. of the duodenum. Ulceration can occur in the postbulbar area of the duodenum. Either the anterior or posterior wall of the duodenum may be in-

involved. Duodenal ulcers on the posterior wall are difficult to demonstrate radiologically. Ulcers of the anterior wall are more likely to perforate than those on the posterior wall. Posteriorly located ulcers are more likely to form a walled-off perforation.

The gross appearance of a gastric ulcer is striking. A chronic gastric ulcer usually has a deep crater with sharp edges and a clean base. The base of the ulcer is whitish-gray and consists of a thickened subserosal coat. If the ulcer perforates to involve adjacent tissues, the base of the ulcer may be formed by these organs (Fig. 36).

Duodenal ulcers are less easily recognized grossly. A small, white, puckered scar on the subserosal coat may provide the only external evidence of the disease. If the ulcer is located on the posterior wall, it may be impossible to diagnose it by palpation. A duodenostomy with inspection of the duodenum may be necessary to learn whether an ulcer is located in this area.

The microscopic features of all peptic ulcers are similar. There is a loss of the mucosa down to the muscularis mucosa. The lining of a typical ulcer crater has four zones: purulent exudate; a thin zone of fibrinoid mucosa; granulation tissue, and an outer dense layer of scar tissue.

Symptoms and Signs. Pain. Pain is the outstanding symptom of peptic ulcer. The pain is frequently sufficiently characteristic to indicate the diagnosis almost without further examination. Ulcer pain has four

CLASSIFICATION OF PEPTIC ULCER

Figure 35. Diagram showing the most frequent locations of peptic ulcer.

Mechanical factors are also important in the development of an ulcer. Ulcers tend to occur where there is a maximum degree of trauma, in the stomach on the lesser curvature and also in the duodenal cap where the acid chyme contents are ejected from the stomach.

Local tissue resistance and defense factors. Local tissue resistance has an important role in the development and location of an ulcer. If only general factors were operative, then the entire lining of the stomach would be digested away by the gastric contents. However, peptic ulcer is a localized disease and it is probable that in an area where an ulcer develops there is some breakdown of the local defense factors. This may be the result of ischemia inasmuch as the neutralizing effect of alkaline blood is an important defense factor. The enzyme systems of the stomach will also contribute to the defense of the mucosa. Urease, which is concentrated in the surface cells of the stomach, catalyzes the breakdown of urea to form ammonia and carbamate, both of which aid in neutralizing parietal secretion.

Systemic and constitutional factors. Hereditary influences, hormonal factors and neurogenic and personality factors all have some bearing on the development of an ulcer. Peptic ulcer is not a hereditary condition, but it does tend to run in families.

The development of ulcers is influenced by local gastrointestinal hormones and by hormones arising in more distant parts of the body. Gastrin, a hormone similar to histamine, produced by the antrum, stimulates secretion of hydrochloric acid. There is no evidence that antral hyperfunction has an important role in the development of peptic ulcer. Enterogastrone, produced by the duodenum, inhibits gastric secretion and gastric emptying. Enterogastrone and similar substances have not been demonstrated to be effective in man in the prevention of ulcer.

Peptic ulceration can occur during prolonged administration of corticotropin or cortisone. This observation has suggested that adrenal hyperfunction may have some part in the etiologic background of peptic ulcer. ACTH markedly increases uropepsin production and also stimulates the production of hydrochloric acid. It has been suggested that stress may induce the hypothalamus to secrete some agents which stimulate the production of the ACTH. Stimulation of the anterior hypothalamus is accompanied by a rise in gastric acidity which can be abolished by a bilateral vagotomy, while

stimulation of the posterior hypothalamus produces an increase in gastric acidity which is eliminated by adrenalectomy.

A pancreatic islet cell adenoma was described in 1955 which appeared to induce gastric hypersecretion and peptic ulceration that resisted every therapeutic measure short of total gastrectomy. This ulcerogenic adenoma of the pancreas islets is composed of non-beta cells and does not secrete insulin.

Study of the clinical cases with ulcerogenic tumors of the pancreas has resulted in the definition of a diagnostic triad: (1) a fulminating ulcer diathesis persists despite the most intense medical therapy, radiation or radical operative procedure short of total gastrectomy. The usually definitive surgical measures, including vagotomy below and above the diaphragm, and the most radical subtotal gastrectomy, have uniformly failed to prevent recurrent ulceration so long as gastric mucosa remains under the influence of this islet adenoma; (2) marked gastric hypersecretion is characteristic with twelve-hour, overnight resting volumes of 2 to 3 liters in the absence of any pyloric obstruction. Acid is uniformly present and often its concentration as well as its volume is very high. Twelve-hour acid production of more than 300 mEq. has been observed as compared to the normal of 18. Such large volumes of secretion promptly recur post-operatively so long as gastric mucosa is retained in the presence of functioning tumor; (3) when a non-insulin-secreting, non-beta cell islet pancreatic adenoma is demonstrated at operation, the clinical triad is complete.

The nature of the influence which the ulcerogenic adenomas exert upon gastric mucosa strongly suggests a hormone. This is so far unidentified but must be powerful and probably acts directly upon the gastric secretory cells. That the pancreas plays a role in gastric secretory function has long been suspected but never proved. If such an influence could be identified, it would have important implications not only for the rare ulcerogenic tumor patient, but also for the great number of patients afflicted with benign peptic ulcer and all its complications.

The sex hormones appear to be related to the development of peptic ulcer. Ulcer is far more common in men than in women. Ulcer is rarely associated with pregnancy.

Acute ulceration of the upper gastrointestinal tract can occur after intracranial injury or disease. These ulcers resemble the acute ulcers following massive infection or in association with burns or other forms of stress.

approximately 15 per cent of patients. It is more common in gastric than in duodenal ulcer. Perforation without previous ulcer distress can occur. This is more frequent with acute ulcers.

Symptoms as related to the location of the ulcer. Esophageal ulcers present substernal pain and dysphagia. Pain in esophageal ulcer

Dysphagia is also common in patients with esophageal ulcer. It is most likely to occur on swallowing solids and is related to the inflammation and spasm in the region of the ulcer. The hiatus hernia, which is usually present, contributes to the dysphagia.

The symptoms of gastric ulcer tend to be less characteristic and more bizarre than those of duodenal ulcer. If an ulcer is located high in the stomach, it may be completely asymptomatic. When the ulcer is flat or shallow, the pain is poorly localized by the patient. Ulcers located in the pyloric channel present bizarre symptoms, nausea and vomiting may be the primary complaints.

The symptoms of duodenal ulcer are rather characteristic. They consist of burning, aching or gnawing sensation located in the epigastrium, usually just to the right of the midline. The pain can usually be localized by covering the site of it with one finger. The pain is usually steady, lasting from fifteen minutes to an hour, and it appears from one to four hours after meals. It is characteristically absent before breakfast.

Ulceration involving the stoma after the performance of a gastroenterostomy differs from the symptoms presented by an uncomplicated ulcer. The pain of marginal or stomal ulcer is located down and to the left from the site of the original ulcer pain. Nausea and vomiting are frequent because of edematous obstruction to the stoma. Loss of weight is common and diarrhea may occur. If either of these is severe, it may suggest the development of a fistula between the stomach, small bowel and colon. Gastroenterocolic fistula fortunately is a rare complication of marginal ulcer, occurring in only about 1 per cent of the patients. In addition to the weight loss and diarrhea, edema due to hyperproteinemia is a common occurrence.

Diagnosis. Diagnosis in peptic ulcer depends primarily on obtaining a typical history of recurrent ulcer distress. Physical examination is much less important. Labora-

tory studies, including gastric analysis and stool examination, may be helpful. Esophagoscopy and gastroscopy have a definite although limited value. The major diagnostic contribution is that of the radiologist who is called upon to confirm the clinical impression of ulcer. In addition, the radiologist can detect ulcers which are asymptomatic and be of value in determining the incidence of complications and the results following therapy.

Physical examination. Physical examination in patients with uncomplicated ulcer may demonstrate no abnormality. Sometimes a patient can point to the area where ulcer pain has occurred. Occasionally there is tenderness on deep palpation over that area. The chief value of physical examination is in excluding other conditions accompanied by physical findings such as an enlarged liver or abdominal masses which might suggest some diagnosis other than peptic ulcer.

Laboratory examination. Gastric analysis is of most value when the physician is confronted with the problem of distinguishing a benign gastric ulcer from ulcerating gastric carcinoma. The usual findings on gastric analysis are hyperacidity with duodenal ulcer and somewhat lower acidity than normal with gastric ulcer. Patients with gastric carcinoma frequently have an acidity. The levels of gastric acidity are of little or no value in differentiating gastric ulcer from duodenal ulcer in the individual patient. Stool examination is also useful, particularly in the differential diagnosis of gastric ulcer and gastric carcinoma. Although occult blood may occur in the stool in patients with benign peptic ulcer, the finding of persistent blood suggests that an ulcerating carcinoma is present. The newest technique in diagnosis is the study of the exfoliated mucosal cells from the lining of the stomach. These may be obtained by lavage, by abrasion or by use of the mucolytic agents. With the latter two methods, the accuracy of distinguishing carcinoma is in the neighborhood of 85 per cent.

Endoscopic examination. Esophagoscopy is of value in differentiating esophageal ulcer from other lesions of the distal esophagus. A hiatus hernia with secondary ulceration of the esophagus is the usual finding, as primary ulcer of the esophagus is rare. Esophagoscopy is of value in the diagnosis and treatment of stricture formation which follows long-standing inflammation of the esophagogastric junction. Some so-called

Figure 36 Photograph of gross specimen showing a chronic gastric ulcer which perforated into the pancreas (Barborka, C J, and Texter, E C, Jr. *Peptic Ulcer—Diagnosis and Treatment* Boston, Little, Brown & Company).

typical characteristics: the nature and intensity, the radiation and location, the rhythm and the periodicity.

Ulcer pain is usually described as a gnawing, aching or burning sensation. It may resemble hunger contractions. It is located in the upper abdomen near the midline and is usually confined to a relatively small area. Pain of duodenal ulcer is better localized by the patient than that arising from gastric ulcer. Pain arising from a marginal ulcer is shifted downward and to the left from the site of the previous ulcer pain. If walled-off perforation occurs, radiation of the pain to the back or other adjacent areas is common.

The rhythmic appearance and disappearance of pain in relation to the state of fullness or emptiness of the stomach is characteristic. The pain usually comes on following a meal from thirty minutes to two hours. It gradually becomes more severe for half an hour or an hour and, if not relieved by medication, the pain may pass off spontaneously. As the ulcer becomes more severe, pain may occur at night. This classically awakens the patient from sleep from one to four hours after retiring, most usually about 1 A.M. Ingestion of food or alkalis at this time will relieve the pain.

Periodicity of the pain also is typical. The pain may be present for days or weeks at a time and then the patient may be symptom free for long intervals. Recurrences are most frequent in the spring or fall months. Recurrences occur in the months in which

greatest temperature change occurs. As the ulcer becomes more severe, the periods of remission between acute attacks become shorter.

Three theories have been proposed to explain the mechanism of ulcer pain. One of these holds that the pain is the direct result of chemical irritation of nerve fibers by the gastric acid, another, that ulcer pain is the result of motor disturbances of the stomach; and the third, that ulcer pain is the result of a combination of both these factors and, perhaps, in association with other factors. The present evidence seems to indicate that, although acid is necessary for the production of an ulcer and ulcer pain, it is probable that some alteration in gastroduodenal motility is necessary for pain to develop. Engorgement of the mucosa of the stomach or duodenum may lower the pain threshold.

Other symptoms. Although pain is the paramount symptom of peptic ulcer, other symptoms can occur. Nausea and vomiting are not common symptoms of the usual peptic ulcer but may result if the ulcer is located in the pyloric channel area or if there is obstruction to the stomach with resultant gastric retention. Constipation may be a presenting complaint, but it is probable that the constipation is more closely related to the type of diet which the ulcer patient takes rather than to the disease per se. Bleeding manifested either by hematemesis or melena may be the initial symptom of peptic ulcer. This occurs as an initial symptom in

ulcer patients. These complications include perforation, walled-off perforation, hemorrhage and obstruction. The majority of bleeding episodes respond readily to medical management and some of the patients with pyloric obstruction respond to medical management. The remainder of the ulcer complications require surgery. This is necessary in approximately 10 to 15 per cent of patients with recurrent peptic ulcer.

Perforation. Perforation is a rare complication affecting about 2 per cent of ulcer patients. It may occur in subjects of any age but is more common in those in the middle years of life. The onset of perforation is marked by the development of sudden, excruciating abdominal pain which may be followed by collapse. The pain may radiate to both shoulders owing to irritation of the undersurface of the diaphragm by free air or gastroduodenal contents. The immediate effect of perforation is the production of chemical peritonitis, but, with the passage of time, the peritoneum becomes infected and the prognosis more serious.

Boardlike rigidity of the abdomen with exquisite tenderness is present on examination. The patient lies still with knees flexed to minimize the pain. The temperature and blood pressure in the early period may be subnormal, but, if bacterial peritonitis supervenes, the temperature may become elevated.

Patients who present similar although less acute symptoms are thought to have subacute perforation. Here the perforation is rapidly sealed over by adhesions with concurrent clinical improvement. Roentgenographic studies show pneumoperitoneum in about two-thirds of patients with acute perforation. When possible, the films should be exposed with the patient sitting up or lying on the left side.

Although the differential diagnosis of a perforated ulcer is seldom difficult, it may be simulated by other conditions. Biliary, renal or small bowel colic presents pain but is not associated with boardlike rigidity. Coronary thrombosis may be differentiated by the radiation of pain to the left shoulder.

The condition which is most difficult to differentiate is pancreatitis. Here, even though severe pain is present, boardlike rigidity is uncommon and shock is less likely to occur. Perforation of the other abdominal hollow viscera can also simulate perforated ulcer.

Walled-off perforation. Walled-off perforation results when the process of perforation

involves ulcers located on the posterior wall of either the stomach or duodenum. Instead of perforating into the free peritoneal cavity, these ulcers penetrate to involve the adjacent structures, most frequently the pancreas and liver. Approximately 5 per cent of ulcer patients develop this complication.

The development of walled-off perforation is marked by either a change in the usual pain pattern, the development of increasingly severe ulcer pain or the radiation of pain to the back. The physical findings do not differ markedly from those present in uncomplicated peptic ulcer. Moderate elevations of the serum amylase may be observed.

The roentgenographic demonstration of a pouch or pocket of air projecting from the stomach is suggestive of a walled-off perforated gastric ulcer. The x-ray signs of a walled-off perforated duodenal ulcer do not differ significantly from those ordinarily present.

The change in clinical features suggests the development of a walled-off perforated ulcer. However, a change in pattern may occur if gastric obstruction occurs or if the patient develops an ulcer in the pyloric channel. Walled-off perforation also must be differentiated from pancreatic disease, biliary tract disease, carcinoma of the colon and disease of the spine.

Hemorrhage. Hemorrhage is the most frequent complication of peptic ulcer. Most ulcer patients have periodic minor bleeding episodes and 20 to 25 per cent have manifest gastrointestinal hemorrhage. The presenting symptom may be hematemesis or melena. Hematemesis, the vomiting of material resembling coffee grounds, is most likely to occur in patients with gastric ulcers or if the hemorrhage is a very large one. Melena is recognized by the passage of frequent bulky black tarry stools.

The clinical manifestations depend upon the amount of blood lost and the rate of bleeding. Pallor is common and, if more than 30 per cent of circulating blood volume is lost, irreversible hemorrhagic shock develops. Endoscopy is rarely carried out during the acute bleeding episode. Roentgenographic studies are also deferred until the acute bleeding is stopped, in most instances. However, if the bleeding is brisk and surgery is considered, roentgenographic study may be carried out without additional risk to the patient.

Hemorrhage from peptic ulcer accounts for 85 per cent of instances of massive gas-

esophageal ulcers may actually be ulcers of the herniated supradiaphragmatic portion of the stomach.

The diagnostic value of gastroscopy is limited to ulcers located in the stomach and even here it may be impossible to visualize an ulcer which is located in the gastroscopically "blind" area. Gastroscopy is also of value in aiding differentiation between apparently benign gastric ulcers, ulcerating malignant lesions and infiltrative lesions of the wall, such as gastritis and lymphoma.

Despite its limitations, the diagnostic examination of a patient with a gastric ulcer is not complete unless gastroscopy is carried out. Recently it has been possible to take a biopsy specimen from the stomach and this has further increased the value of this procedure.

Röntgenography. The roentgenographic signs associated with ulceration depend somewhat on the location of the ulcer. In esophageal ulcer, one may find a fleck of barium adhering to the esophageal wall. The majority of esophageal ulcers are associated with some other disorder, most frequently hiatus hernia. The roentgenographic diagnosis of esophageal ulcer is difficult.

The primary sign of gastric ulcer is the demonstration of a niche or bud projecting from the stomach. The niche is usually rounded and has a comparatively smooth outline. Rarely, the contour may be irregular even though the lesion is benign. Size, which was once considered to be a valuable criterion in distinguishing between benign and malignant ulcers, is of little value. Indirect signs of ulceration may be present, including localized spasm opposite the ulcer, alterations of the rugal folds about the ulcer and localized tenderness in the region of the ulcer. Motor disturbances may also be observed and, if the ulcer is near the pyloric channel, gastric retention can result. If the ulcer is situated higher in the stomach, hyperperistalsis may be observed.

The roentgenographic signs of ulceration in the upper portion of the stomach above the incisura angularis are more easily delineated than those below the incisura angularis. Gastritis of the antrum is frequently present with ulcers below the angularis. Direct evidence of a crater is difficult to obtain and frequently the diagnosis must be based on indirect or secondary signs of ulceration.

The direct sign of a duodenal ulcer is the demonstration of a deformity in the outline of the duodenum. The deformity may as-

sume a variety of patterns, including niche formation, retraction in the region of the niche, a defect in the curvature opposite the niche, an eccentrically placed pyloric lumen and pseudodiverticular dilatation. The most commonly observed deformity is a pinching in of the sides of the duodenum which ultimately form the clover-leaf pattern. A crater may be demonstrated at the middle of the clover-leaf with folds radiating into it. Indirect signs of duodenal ulcer include irritability of the duodenum, active gastric peristalsis and reflex gastric spasm. Localized tenderness at the site of the duodenal ulcer itself is of little value in the diagnosis of a duodenal ulcer.

The x-ray study is of particular value in following the progress of healing of gastric ulcers but is of little value in following the progress of duodenal ulcer. Once a deformity has developed in the duodenum, it is likely to become persistent regardless of whether the ulcer is healed or not.

There are definite limitations to the value of the roentgenologist in the diagnosis of peptic ulcer. Alterations in the stomach or duodenum may be present from extrinsic causes and not as the result of primary ulceration. The roentgenologist may acknowledge that the interpretation of the roentgenographic findings depends partly on the patient's clinical history and not entirely on what is demonstrated on the films.

Differential Diagnosis. Even though the clinical picture of ulcer is fairly characteristic, on occasion it must be differentiated from a variety of conditions. Among these are hiatus hernia, esophagitis, atrophic gastritis, hypertrophic gastritis, carcinoma of the stomach, gallbladder disease and conditions involving the pancreas and intestines.

The most important conditions to be differentiated are those of nonulcer dyspepsia and carcinoma of the stomach. Nonulcer dyspepsia, or functional dyspepsia, denotes symptoms suggesting ulcer in patients in whom no definitive evidence of ulceration can be established. Patients with gastritis may present similar symptoms. Both these groups of patients differ from ulcer patients in that they fail to obtain complete symptomatic relief, although they are improved by being placed on the dietary and medical management. Ulcerating carcinomas may simulate a benign gastric ulcer and render a differential diagnosis difficult.

Complications. Complications which require specific attention and hospitalization develop in approximately 20 per cent of

the stomach are necessary to distinguish benign gastric ulcer from ulcerating carcinoma. The gastric acidity in gastric ulcer is usually lower than normal but not as low as the anacidity frequently present with carcinoma. Persistent failure to demonstrate acid after histamine stimulation in the presence of a gastric crater strongly suggests that the lesion is malignant.

The persistence of occult blood in the stool is unusual in patients with benign gastric ulcer and again suggests that the patient has a malignant process.

The study of exfoliated cytologic material from the stomach is of great value in distinguishing ulcerating carcinoma from a benign gastric ulcer. The material, which is an of the cells

differ in their cytologic characteristics, having larger, more deeply staining nuclei and other evidences of malignant change.

If the gastric lesion is in a gastroscopically visible area, gastroscopy can be of immense value. The benign gastric ulcer presents a punched-out appearance with smooth edges and a clean-looking base, whereas the malignant ulcer may have heaped-up edges, irregularities of the margin and evidence of bleeding.

Three-quarters of all gastric craters occur along the lesser curvature of the stomach.

The prepyloric area is also a common site for benign ulcers and benign ulcers also occur in the cardiac portion of the stomach and in the pylorus. Certain criteria are useful in distinguishing malignant from benign ulcer. The malignant ulcer frequently presents a meniscus effect with the crater being superimposed on the top of a filling defect projecting into the stomach. Alterations in the pliability are frequent in malignant ulcer. Size is not a very useful criterion in distinguishing benign from malignant lesions. Occasionally one sees extremely large benign ulcers (Fig. 37).

The response to treatment is useful in distinguishing between benign and malignant ulcers. Even though malignant ulcers may show some improvement and decrease in size, they do not go on to complete healing such as occurs with most benign ulcers. Perforated walled-off ulcers may not heal despite good medical management.

Treatment. General considerations. The aims of treatment are threefold: to relieve symptoms, to heal the ulcer and to prevent recurrences. Relief of symptoms is achieved rather easily, but complete healing of the ulcer requires more prolonged and intensive treatment. Approximately forty days are necessary for the healing of an ulcer. The prevention of recurrences is a still more difficult problem.

Good ulcer management is based on rest and sedation, diet, the use of antacids and

Figure 37. A, X-ray appearance of large benign gastric ulcer. B, X-ray appearance of same ulcer two weeks later showing healing (Barborka, C. J., et al. *Quart. Bull., Northwestern Univ. M. School*, vol. 28).

trointestinal bleeding. It must be differentiated from bleeding as a result of esophageal varices, carcinoma or blood dyscrasias. The bromsulphalein test is valuable in distinguishing bleeding from esophageal varices from bleeding from peptic ulcer. Bromsulphalein retention is likely in cirrhotic patients but rarely is persistent in patients with bleeding peptic ulcer. Bleeding can also occur from gastritis or hiatus hernia.

Obstruction. Transient obstruction of the distal portion of the stomach is a fairly common complication of ulcer. Edema, spasm and stenosis of the pyloric segment may all contribute to the gastric retention.

The initial clinical features of obstruction are not characteristic and the diagnosis may be made only after roentgenographic examination or aspiration of the stomach. As the obstruction becomes more severe, changes in the character of ulcer distress may be observed. The pain has less relation to meals. Breakfast is the best-tolerated meal of the day and the patient complains of increasing fullness as the day goes on. Vomiting may occur in the late evening or early hours of the morning. The vomitus usually contains food remaining from the previous meal. Weight loss and dehydration are late signs of obstruction. Visible peristalsis which passes from the left to the right is characteristic of obstruction at the pylorus.

The barium meal is valuable in determining whether obstruction is present. Pyloric obstruction is present if there is significant gastric retention at six hours, or any retention at twenty-four hours. Retention of more than 100 ml. of gastric secretion in the fasting stomach, or more than 750 ml. during the twelve-hour overnight period of continuous suction, is usually indicative of gastric retention and obstruction.

Gastric retention due to an obstructing ulcer can be simulated by obstructing carcinoma of the distal stomach and hypertrophic pyloric stenosis. Pyloric channel ulcers are likely to cause delay in gastric emptying.

Gastric Ulcer and the Ulcer-Cancer Problem. *Differences between gastric and duodenal ulcers.* Gastric ulcer is clinically less frequent than duodenal ulcer, although autopsy statistics indicate that the frequency of the two lesions is identical. Gastric ulcers tend to come on at a later age than do duodenal ulcers. The etiologic factors also differ. The acidity in gastric ulcer patients is lower than in normal individuals and consider-

ably lower than the elevated values seen in duodenal ulcer patients. The pathogenesis of gastric ulcer seems to be related more to decreased mucosal resistance of the stomach than to overactivity of the aggressive acid-pepsin interaction. This observation is also supported by the fact that gastric ulcers occur in the area of the stomach subject to most trauma and supplied least well with blood.

Relation to gastric carcinoma. Because of the not infrequent association of gastric ulcer and gastric carcinoma, it has been suggested that gastric ulcers may undergo malignant degeneration. There is no proof of this concept and it is now believed that malignant ulcers were malignant from the beginning and not the result of degeneration of a previously benign lesion. The problem is one of differentiating the ulcerating malignant lesion from a benign gastric ulcer. The reported incidence of malignant ulcer in patients having apparently benign lesions varies between 8 and 20 per cent. Smith, Boles and Jordan, reporting on 1000 patients with the clinical diagnosis of benign gastric ulcer, noted that 8.8 per cent of these patients ultimately were found to have ulcerating malignant lesions. The incidence of malignancy was 16 per cent in patients who developed a recurrent ulcer. The accuracy of diagnosis is improved by the more frequent use of exfoliative cytologic examination. If gastric ulcer patients are studied carefully, including exfoliative cytologic study, with the specific aim of excluding patients who have malignant ulceration, the error in diagnosis should be very small—perhaps as low as 1 per cent.

Diagnosis of gastric ulcer. The diagnosis of gastric ulcer is based upon the clinical features presented by the patient, roentgenographic study of the lesion, gastroscopic findings and a study of exfoliated cells from the stomach.

The history presented by the gastric ulcer patient resembles that of the duodenal ulcer patient except that it is less characteristic. If the ulcer is located high in the stomach, it may be asymptomatic. Ulcers located in the distal end of the stomach are frequently not recognized as such since the major complaint of these patients is nausea and vomiting.

The physical examination is of little value. Localized tenderness may be present if the ulcer is located in an area which is accessible to palpation.

Gastric analysis, stool examination for occult blood and study of exfoliated cells of

relationship with sympathetic understanding of the patient's problems is essential to good management. Mental and emotional conflicts have an important bearing on recurrences. Occasionally a change in environment or occupation may be necessary. If the patient can be convinced that he will be a more productive individual if he remains healthy by taking annual vacations and long week ends and by finding other outlets for his energy, much can be accomplished.

Medical treatment of uncomplicated ulcer. For the patient with only occasional mild distress, only moderate restrictions are necessary. These consist of the use of an ambulatory diet with interval antacids and sedation. For patients with moderately severe distress which is not responding to simple management, the addition of the anticholinergic drugs to the above-described program frequently produces symptomatic relief. However, if symptomatic relief is not achieved promptly, the patient should be hospitalized where he can be treated under optimum conditions.

Medical treatment of complicated ulcer.
PERFORATION. Closure of perforation as soon as possible after the diagnosis is established is indicated for perforated ulcer. On occasion, gastric resection is deemed advisable if the patient has had previous perforations or if the closure of the perforation presents technical difficulties. The mortality rate of perforated ulcer is below 5 per cent. It rises with increasing time after perforation.

The expectant-suction method of treatment of perforated ulcer should be limited strictly to patients having had perforation many hours prior to the institution of treatment or to those in whom surgical closure cannot be undertaken. Antibiotics are administered concurrently. Increasing rigidity and tenderness are indications for operative intervention.

WALLED-OFF PERFORATION. Intensive treatment in the hospital is indicated for patients suspected of having a walled-off perforated gastric or duodenal ulcer. Overnight gastric suction and the ulcer I diet during the daytime may be supplemented by anticholinergic drugs. Many of these patients are refractory to the most rigid medical program and surgical treatment becomes necessary. The major indication for surgery is intractability, although some of these patients also have had previous bleeding or obstruction.

HEMORRHAGE. The bleeding patient should be hospitalized and checked for the presence of shock. The blood pressure and pulse

should be recorded at hourly intervals and the patient's blood typed and crossmatched in the event transfusion should be necessary. The hematocrit reading or hemoglobin estimation should be made on admission and periodically thereafter, to follow the status of the hemorrhage. Elevation of the blood urea nitrogen will also result if significant bleeding exists. Another index of the degree of bleeding is the number of stools passed daily. The blood in the stools acts as an irritant and more frequent stools occur while the patient continues to bleed.

If there are signs of shock, an infusion should be started while whole blood is being obtained. If the blood volume decreases in spite of administration of blood, it indicates that hemorrhage is proceeding at a rate faster than the blood is replaced and surgical therapy must be considered.

Dietary treatment, either of the ulcer I type or the Meulengracht type of diet, may be started as soon as the patient feels able to eat.

Although the majority of bleeding patients respond to medical management, surgery may be necessary for patients who are bleeding more rapidly than blood can be replaced. The best results in treating bleeding ulcer patients are obtained when the medical and surgical departments act as a team. The mortality rate is lower if surgery is carried out in the interim phase rather than when the patient is acutely bleeding.

OBSTRUCTION. The medical treatment of pyloric obstruction consists of aspiration of the stomach in conjunction with giving a liquid diet and the administration of antacids and antispasmodics. Electrolyte disturbances are less prone to occur if intermittent aspiration, such as overnight suction, is used rather than continuous aspiration. The tube may be removed during the day and the patient fed a liquid diet of milk and cream at hourly intervals and given antacids according to the ulcer I program. The amount of aspirate obtained during each twelve-hour period serves as an index of the progress of treatment. Roentgenographic study, which can be repeated at intervals of five to seven days, also can be utilized to determine whether progress is being made with treatment.

Surgical treatment is necessary for patients who do not respond to medical management. Correction of nutritional problems and electrolyte disturbances must be carried out prior to the surgical treatment. The operations most frequently performed are gas-

anticholinergic agents, restrictions of coffee, alcohol and tobacco, and the use of psychotherapy.

Rest and sedation. Rest is essential to good ulcer management. It is desirable that treatment be carried out in the hospital where the patient is separated from environmental stress. Hospitalization in addition to providing rest also has other advantages. It enables the physician to teach the patient the basic principles of ulcer treatment which are essential to maintaining a satisfactory program. Sedation obtained by means of phenobarbital, 30 mg three or four times a day, is usually prescribed.

Diet. Dietary treatment is based on avoiding foods which stimulate the secretion of hydrochloric acid; the administration of foods which neutralize gastric acid, and elimination of irritating foods from the diet. The dietary principles of most ulcer programs are similar. They represent modifications of the Sippy-type diet which are used in combination with antacid drugs. In most hospitals, ulcer diets are divided into ulcer I, ulcer II and ulcer III diets. The ulcer I diet consists of 3 ounces of a mixture of half milk and half cream given every hour during the day. One of the nonabsorbable antacids is administered every hour on the half-hour. This diet is usually continued for one or possibly two weeks. It is deficient in vitamins and minerals, particularly the vitamin B and C groups. The second-stage ulcer management, ulcer II, permits the addition of bland foods such as cheese, eggs and cereal, so that the patient now is taking a morning, midday and evening meal with interval feedings of milk and cream and antacids being continued. The second-stage diet is usually continued for about one or two weeks, at which time the patient is shifted to the ambulatory-type program, ulcer III. This diet includes puréed vegetables, baked potato, baked apple and certain meats. Raw fruits and vegetables, highly seasoned foods and extremely hot or cold liquids are excluded.

Antacids. Antacids are substances which lower the acidity of the gastric contents. The most commonly employed antacids are calcium carbonate and the aluminum and magnesium compounds. Calcium carbonate is given in 2- to 4-gm. doses. It has a tendency to produce constipation and magnesium carbonate or magnesium oxide must be given from time to time. The combination of calcium carbonate with magnesium oxide and milk has good neutralizing capacity.

Aluminum hydroxide, which is frequently combined with magnesium trisilicate to combat the constipating properties of aluminum hydroxide, is the most commonly used. Neutralization of gastric acidity by aluminum hydroxide is not great, but this compound does have demulcent properties as does magnesium trisilicate. The usual dose is 15 to 30 cc. The most effective tablet antacid is dihydroxy aluminum aminoacetate, which is taken in 1-gm. doses.

The frequency of antacid administration varies with the severity of the ulcer and the type of management. With first-stage management, antacids are given at hourly intervals from 7:30 A.M. until 9:30 P.M. When second-stage management is used, the antacids are continued at hourly intervals between meals but omitted at mealtime. When used with ambulatory program, antacids may be given one-half hour before meals and an hour and a half after meals or at any other time the patient has ulcer distress.

Anticholinergic agents. These agents can be divided into two groups: the tertiary amines, such as atropine, and the quaternary amines, such as methantheline. These agents decrease gastric secretion and inhibit gastrointestinal motor activity. It is recommended that they be employed as adjunct therapy along with the diet, antacids and sedation. They are not necessary for all patients. Symptomatic relief following their use is usually gratifying, but the eventual course of the patient with peptic ulcer is not altered by their long-term administration. They are administered in dosage of from one to two tablets four times a day prior to meals and bedtime. The anticholinergic agents are contraindicated in the presence of hemorrhage, pyloric stenosis and suspected perforation and in patients with prostatic hypertrophy or glaucoma.

Restriction of coffee, alcohol and tobacco. Most physicians feel that better ulcer management is achieved with the curtailment or elimination of coffee, alcohol, caffeine-containing beverages and smoking.

There are many excellent studies on the relationship of smoking to peptic ulcer. It appears unlikely, however, on careful analysis of the varied statistics, that smoking is an important and direct cause of the disease. On present evidence, it seems more reasonable to suggest as a working hypothesis that the effect of smoking is to interfere with the healing of the ulcer and to help maintain its chronicity.

Psychotherapy. A good physician-patient

quate medical management should be considered for surgery. Many of these patients have walled-off ulcers which respond very poorly to medical treatment.

SUSPICION OF CARCINOMA. Patients with gastric ulcers which do not heal within a brief time with medical management in the hospital, or who present clinical criteria suggestive of malignant disease, are candidates for surgery. The operation of choice is gastric resection with removal of the ulcer.

COMPLICATIONS SECONDARY TO PREVIOUS SURGERY. Surgical treatment is necessary for many patients with marginal or recurrent ulcer which followed previous gastroenterostomy or gastric resection. It also is occasionally necessary to operate in order to revise previous surgical results in an attempt to eliminate severe postsurgical disability.

CHOICE OF OPERATION. The most commonly employed operation is gastric resection, either of the Billroth I or II type. The commonly employed forms of this are shown in Figure 38. Section of the vagus nerves in conjunction with a drainage operation, either gastroenterostomy, gastric resection or pyloroplasty, is also employed. Wangensteen has suggested the use of tubular resection of the stomach in an effort to maintain gastroduodenal continuity and minimize postsurgical complications.

COMMON TYPES OF GASTRIC RESECTION

Figure 38. Diagrammatic representation of commonly employed types of gastric resection (Barborka, C. J., and Texter, E. C., Jr. *Peptic Ulcer—Diagnosis and Treatment*. Boston, Little, Brown & Company).

Results of Surgery. Esophageal ulcer. Massive hemorrhage, perforation, intractability to medical management and stricture formation may all require surgery. The procedures employed include correction of hiatus hernia, partial resection of the esophagus, subtotal gastrectomy and vagotomy and gastroenterostomy. The results of surgery for esophageal ulcer are fairly satisfactory.

Gastric ulcer. Surgical treatment in gastric ulcer is very satisfactory. Marginal ulcer is rare. The mortality rate is approximately 5 per cent.

Duodenal ulcer. After an adequate resection of two-thirds to three-quarters of the stomach, approximately 85 per cent of patients will have satisfactory results. Marginal ulcers can be expected to develop in 4 to 8 per cent of patients and an additional number have postoperative complications. The average mortality rate is between 3 and 5 per cent.

On the basis of a shorter follow-up period, the results of treatment following vagotomy and gastroenterostomy appear to be about as satisfactory, with 85 per cent of patients obtaining a good result. Recurrences take place in approximately 5 per cent of patients and postoperative complications, mainly diarrhea, occur in an additional 7 per cent. The operative mortality is about 1 per cent. The operations of partial gastrectomy and vagotomy have also been combined with encouraging initial results.

Marginal ulcer. The surgical treatment depends upon the type of surgery previously employed. In the presence of a gastroenterostomy, the gastroenterostomy should be taken down and adequate resection of either the Billroth I or II type should be performed. Vagotomy may be performed in addition to gastric resection. If the marginal ulcer followed an adequate resection, the ulcerated area should be resected and a vagotomy performed. The results of treatment after these procedures are satisfactory.

Postsurgical Management. Careful postsurgical management is necessary to prevent the development of complications. Dietary treatment should be continued for a variable time after surgery. If the diet is liberalized too rapidly after operation, symptoms may develop which are related to the altered size of the stomach and its lack of storage capacity.

Marginal ulcers may develop after either gastric resection or vagotomy and gastroenterostomy. Approximately 1 per cent of pa-

tric resection with or without vagotomy, or gastroenterostomy and vagotomy.

Philosophy of Ulcer Management. Medical treatment should be the basic treatment for gastric ulcer with surgery being reserved for patients whose ulcers do not heal or who present evidence of malignant disease. Many surgeons, however, advocate surgery for all gastric ulcer patients.

The arguments presented in favor of immediate operation for all gastric ulcer patients are as follows. There has been little improvement in the survival rate of patients with carcinoma of the stomach owing primarily to failure to make a diagnosis and obtain surgical care before metastasis developed. Radical resection in all patients with gastric ulcer before the diagnosis of cancer becomes obvious may salvage an appreciable number of patients, even though many so treated cannot be proved to have had a malignant ulcer. One cannot make a distinction between benign and malignant ulcer with sufficient accuracy to permit conservative treatment and continued observation. The results of gastric resection for gastric ulcer are uniformly good. To delay surgery until the results of medical treatment become evident is hazardous as far as the optimum time for resection is concerned.

A case can also be made against immediate surgical intervention. Even though there are no diagnostic criteria absolutely indicative of benignancy, the diagnosis can be made with a high degree of accuracy. Complete remission of all signs and symptoms, with the disappearance of the ulcer as demonstrated by x-ray findings and gastroscopy, the presence of free acid and the disappearance of occult blood in the stool, all suggest that the patient has a benign lesion. Patients without evidence of malignancy should be given a trial of four to six weeks of strict medical management in the hospital. This period is not sufficiently long to alter the five-year cure rate for carcinoma which is low to begin with. If the patient's ulcer does not heal within this time, surgery is then recommended.

If, however, the patient has persistent achlorhydria with histamine administration, a positive Papanicolaou smear, evidence of roentgenographic changes suggestive of a malignant lesion or an ulcer on the greater curvature or in the prepyloric region, immediate operation should be advised. The diagnostic error of mistaking an ulcerating malignant lesion for a benign lesion should be at least as low as the usual surgical mor-

tality, namely, 3 to 5 per cent, and, in the experience of some utilizing the recent diagnostic aids, the error in diagnosis may be as low as 1 per cent.

Patients with gastric lesions must be hospitalized and maintained in the hospital either until complete healing takes place or until a decision can be made as to whether surgery should be employed. Careful study in the hospital, including frequent roentgenographic examinations, gastroscopy, exfoliative cytologic study of the material of the stomach, stool examinations for occult blood and gastric analysis are essential to a complete diagnostic work-up. The time allowable for medical treatment of a gastric ulcer varies somewhat, but usually a decision can be made within four to six weeks.

If healing of a gastric ulcer does not take place promptly with intensive medical management, surgical intervention is indicated. The operation of choice is gastric resection, including resection of the ulcer. Vagotomy may be carried out concurrently. Both the modifications of the Billroth I and Billroth II operations have been employed.

Surgical treatment. Surgical treatment is necessary for between 10 and 15 per cent of patients with chronic or recurrent peptic ulcers. Indications for surgical treatment are perforation, obstruction, hemorrhage, failure of medical management or intractability, suspicion of carcinoma and complications secondary to previous surgery.

PERFORATION. Surgical closure of a perforated ulcer is indicated as soon as the diagnosis is established. Simple closure is usually employed, although on rare occasions more definitive gastric surgery may be necessary.

OBSTRUCTION. Surgical treatment is necessary if the obstruction is persistent and does not respond to medical treatment. The operations employed are gastric resection with or without vagotomy, and vagotomy with gastroenterostomy.

HEMORRHAGE. As the majority of patients with hemorrhage respond to medical management, surgery is necessary only for those patients whose bleeding is prolonged or recurrent. Surgery should be considered if the patient has had more than one massive bleeding episode. Continuous hemorrhage in patients over fifty-five years of age usually requires surgical treatment. The operations of choice are subtotal gastric resection or partial resection with vagotomy.

INTRACTABILITY. Patients who have continued distress and disability despite ade-

treatment. They compared the results of medical and surgical treatment in 498 patients with chronic gastric ulcer. One-half were treated medically, the remaining being treated surgically. Satisfactory results were obtained in 80 per cent of the surgically treated patients, moderately successful results in 10 per cent and poor results in the remaining 10 per cent. Three-quarters of the patients in the medically treated series developed a recurrence during the period of study. On the basis of Swynnerton and Tanner's study, earlier surgery might be advised for the gastric ulcer patient, since a recurrent ulcer constitutes a strong indication for immediate surgery.

The inciting causes for recurrence are physical and mental fatigue, emotional disturbances, dietary indiscretions and infections. Specific measures have been utilized in an attempt to prevent recurrences. These include the use of enterogastrone and related substances, the use of radiation and the long-term administration of anticholinergic drugs. There is some suggestion that radiation might be of some value, but neither enterogastrone nor the anticholinergic drugs have been effective in preventing recurrences.

It is apparent that the major problem in peptic ulcer is the management of recurrences. The education of the patient in the nature and course of the disease is of great value. The resolution of occupational problems and the demonstration of the relationship between ulcer distress and the patient's personality are both valuable in preventing recurrences. The maintenance of dietary restrictions, the avoidance of food and drugs which stimulate gastric secretion and the prompt treatment of infections would all appear to be equally important. It is also thought that the prompt treatment of a recurrence is of value in minimizing the length of the recurrence and preventing the subsequent development of complications.

However, approximately 90 per cent of ulcer patients can be managed satisfactorily medically. Of the remaining 10 per cent who require surgery, approximately 90 per cent of these achieve satisfactory results. It can be seen, therefore, that with proper medical and surgical cooperation satisfactory results can be achieved in the vast majority of patients with chronic peptic ulcer.

BENIGN GASTRIC LESIONS

Foreign Bodies in the Stomach. Almost y small foreign body may be accidentally

ingested and lodge in the stomach. Two types of objects may be found within the stomach. The first of these—individual objects—commonly includes coins, marbles, pins, needles and other small objects. The second class—the bezoars—consists of a conglomeration of indigestible swallowed material. The most common of these is a trichobezoar or hairball, which consists of matted swallowed hair. Another common type is a phytobezoar. Phytobezoars are the result of accumulation of vegetable fibers and most commonly follow the ingestion of persimmon seeds.

Most foreign bodies in the stomach are the result of accidental ingestion. However, there are circumstances in which foreign bodies are ingested deliberately. This is particularly true in insane or psychopathic people who may swallow any variety of small object. There is also that small group of people who earn their living as side show freaks by swallowing broken glass, razor blades and the like.

Symptoms. Foreign bodies in the stomach seldom cause symptoms unless complications arise. Complications include obstruction, ulceration, perforation and hemorrhage. Gastric ulcers are not uncommonly seen in association with bezoars. If the object becomes large enough, obstructive symptoms may result.

Diagnosis. Radiopaque objects in the stomach can be demonstrated by x-ray examination. Some nonradiopaque objects, such as bezoars, can be seen because of the characteristic shadow which is present on the x-ray film. Gastroscopy can also be utilized to visualize foreign bodies within the stomach.

Treatment. Foreign bodies can be handled conservatively in most instances, as most of them will pass spontaneously. The addition of mineral oil and bulky, well-cooked foods into the diet may be of some aid in the passage of sharp-pointed objects. If the object constitutes a menace to the patient because of the possibility of perforation, laparotomy can be performed and the object removed. Operations also mandatory if the foreign body is producing obstruction or hemorrhage.

Gastritis. Gastritis is an inflammation of the gastric wall due to a variety of causes. The early descriptions of gastritis were based upon the gastroscopic appearance of the stomach, whereas in more recent years the descriptions have been supplemented by pathological material from the stomach.

tients developing a marginal ulcer may develop a gastroenterocolic fistula. The treatment for gastroenterocolic fistula is division of the fistula, closing the opening into the colon. Resection of the stomal ulcer is then carried out in a manner similar to that employed in patients with marginal ulcers.

The symptoms which follow gastrectomy may be classified as follows: the dumping syndrome, symptoms due to alterations in carbohydrate absorption, postgastrectomy anemia, postoperative weight change, and miscellaneous syndromes, including the development of vitamin deficiencies and postoperative gastritis.

The most serious of these is the dumping syndrome. The dumping syndrome may be defined as the occurrence of sweating, warmth, flushing, nausea, palpitation and faintness with or without diarrhea, which develops shortly after ingesting a meal. It is relieved by lying down. The incidence of the dumping syndrome varies from about 5 to 12 per cent after adequate gastric resection. It is thought to be due to rapid, uncontrolled emptying of large amounts of unprepared food into the jejunum. Meals with concentrated carbohydrate are the most likely to provoke an attack. Machella has simulated this syndrome by instilling protein hydrolysate or magnesium sulfate into the jejunum. Increased motor activity and distention of the jejunum have both been implicated as causative factors. The dumping syndrome is also influenced by the size and type of the gastroanastomosis. It is less frequent when the Hofmeister modification of the Billroth II or the Schoemaker modification of the Billroth I operation is used. The symptoms of the syndrome are similar to those produced by anxiety and it appears that the syndrome is most likely to occur in obviously neurotic individuals.

The avoidance of foods with high carbohydrate content, the avoidance of drinking fluids during meals, and either eating while lying on the left side or lying down shortly after eating, have all been recommended for treatment. In patients with severe symptoms, the Billroth II type of anastomosis is sometimes converted into a Billroth I, utilizing the interposition of a small jejunal loop.

Rapid absorption of glucose from the small bowel may be followed by hypoglycemia two or three hours after eating. The hypoglycemic attack is manifested by hunger, weakness, sweating and tremor, physical exercise usually being the precipitating factor. These symptoms are seldom disabling, but the patient's condition can be improved

by the administration of a high protein diet which minimizes the fluctuations in blood sugar concentration.

Postgastrectomy anemia may result from poor absorption of iron. It can be corrected by the administration of iron even in the presence of achlorhydria. Postgastrectomy patients may have difficulty in gaining weight in the postoperative period. This is more likely to occur with the Billroth II than with the Billroth I operation. Zollinger has suggested that more conservative procedures be employed in patients who are underweight prior to surgery, either a 60 per cent Billroth I resection combined with vagotomy, or vagotomy and a posterior gastroenterostomy.

Vitamin deficiencies are not uncommon after gastric resection.

Patients who have a high gastrectomy may develop postoperative gastritis as a result of the reflux of alkaline juices into the gastric pouch. The alkaline juices may have to be diverted away from the stomach.

The major symptom following vagotomy combined with an adequate drainage operation is the development of diarrhea. The cause is not known, but it is thought that it is probably due to altered motor function of the stomach and upper small bowel. It occurs in about 7 per cent of patients and it can be managed by nonspecific measures used for the treatment of diarrhea.

Course and Prognosis. The clinical course of peptic ulcer differs from that of many other conditions in that it is characterized by long periods of complete, or nearly complete, freedom from symptoms alternating with shorter periodic recurrences of ulcer distress. Even though the long-term results of treatment are considered favorable by most physicians, the recurrence of ulcer symptoms at some time may be anticipated in the majority of patients who have a chronic peptic ulcer. Between 10 and 36 per cent will have a recurrence within the first six months after a course of medical treatment, while the incidence of recurrences rises at the end of the fifth year to between 46 and 93 per cent.

The results of treatment in gastric ulcer are thought to be somewhat more favorable than in duodenal ulcer. Smith, Boles and Jordan reporting on their experience with 1000 patients with apparently benign gastric ulcer indicated that of 397 patients treated medically, 75 per cent had good results, 14 per cent had fair results and 11 per cent had poor results.

However, Swynnerton and Tanner were less optimistic about the results of medical

Gastritis often follows operations for gastric or duodenal ulcer. This postoperative gastritis appears to be the result of the reflux of the alkaline intestinal contents into the stomach. It usually subsides without treatment. Postoperative gastritis is not different from other forms of gastritis; it may be acute or chronic and there may not be erosions or superficial ulcerations. Biopsy of the gastric remnant helps very much in determining the degree of gastritis. Sometimes the gastroscope and the biopsy forceps may be introduced through the stoma into the jejunum and a diagnosis of normal jejunal mucosa or jejunitis may thus be established.

Gastric Atrophy. Partial or complete gastric atrophy tends to occur with advancing age and, with it, hypoaclidity or anaclidity. Gastric atrophy may exist as an independent entity but is also commonly seen in pernicious anemia. The diagnosis of gastric atrophy can be made by gastroscopy when the mucosa appears pale, thin and with numerous easily visible blood vessels. Gastroscopic biopsy and gastric atrophy may be hazardous. If the mucosa is exceedingly thin, biopsy is not recommended. However, if the diagnosis of gastric atrophy is doubtful on gross gastroscopic inspection, gastroscopic biopsy may be performed; this must be done with great care. In this way a firm pathologic diagnosis may be established.

Specific Inflammations of the Stomach.

Gastric syphilis. Syphilis may involve the stomach by the development of a gumma. Depending upon the frequency and appearance, a gumma may simulate gastric ulcer or carcinoma. Roentgenographic changes have also been described in association with tuberculous crises.

The symptoms may suggest those of either peptic ulcer or carcinoma.

Gastric syphilis responds to antisyphilitic therapy.

Tuberculosis of the stomach. Tuberculosis may involve the stomach to produce an ulcerating lesion. This may simulate benign ulcer, carcinoma or syphilis. It is a rare condition. The treatment is surgical with resection of the involved portion of the stomach.

Other inflammatory conditions. Hodgkin's disease, actinomycosis and other fungus infections may involve the gastric mucosa. They are extremely rare.

Hypertrophic Stenosis of the Pylorus. Hypertrophic stenosis of the pylorus is an obstructive narrowing of the pylorus due to hypertrophy of the pyloric muscle. It is most

commonly seen in infants but is occasionally seen in adults.

Infantile type. Pyloric stenosis is recognized in infants usually when they are about two to three weeks of age. It is more common in males than in females. At operation, the pylorus is seen to be enlarged and of cartilaginous consistency.

The symptoms consist of projectile vomiting accompanied by weight loss. Occasionally the enlarged stomach can be seen and rarely a tumor representing the pylorus can be palpated.

Conservative treatment should be tried using antispasmodic-sedative mixtures along with thick cereal feedings. If the patient does not respond to this treatment, the performance of a Ramstedt-Fredet pyloroplasty is indicated. This consists of a longitudinal incision through the pyloric muscle down to the mucosa. The results of treatment are gratifying.

Adult type. Hypertrophy of the pylorus is occasionally seen in adults. It is also termed "acquired" pyloric stenosis because of its frequent association with gastric diseases, such as gastric ulcer or gastritis. Ulcers located within the pylorus are most prone to produce this syndrome.

The primary symptom is vomiting which may or may not be accompanied by pain. Roentgenologically, the stomach may appear dilated and shows marked delay in gastric evacuation.

Treatment depends upon the underlying condition. If a gastric ulcer is present, the medical management for gastric ulcer should be followed. If an ulcer is in the region of the pylorus, medical management may not be satisfactory and gastric resection or gastroenterostomy and vagotomy may be necessary.

Prolapse of the Gastric Mucosa. Prolapse of the gastric mucosa consists of the prolapse of the mucosa of the distal stomach through the pylorus into the duodenal bulb. There is considerable difference of opinion as to whether this condition produces symptoms and what treatment should be recommended for it. It appears to be more commonly associated with hypertrophic gastritis, particularly of the antral area. Many workers feel that it is a normal physiologic variant, being seen as often in patients without symptoms as in those with symptoms. Conservative treatment is indicated.

Prolapse of the gastric mucosa is ordinarily a medical problem and in only the severe

Many classifications of gastritis have been suggested. From the point of view of the gastroscopist only three groups are important, namely, acute gastritis, chronic gastritis and gastric atrophy. Since the advent of gastroscopic biopsy it has become obvious that the pathologist can differentiate only these three. The terms "superficial gastritis" and "hypertrophic" gastritis, which have been used so long in gastroscopic interpretation, cannot be definitely correlated with the pathologic findings.

We believe the term "hypertrophic" gastritis is a misnomer and should be abandoned, since the verrucous appearance of the gastric mucosa, which upon gastroscopy appears to be chronically hypertrophic is associated with a normal histologic picture in most cases. This finding indicates that the verrucous nature of the mucosa is probably a normal variant.

Acute gastritis. SIMPLE EXOGENOUS GASTRITIS. Acute gastritis is a common condition usually of brief duration. It develops as a result of ingested foods or other irritants. Gastroscopically it is characterized by the presence of reddening, edema, superficial erosions and adherent slimy, white mucus. This type of appearance has been considered diagnostic of "superficial" gastritis, which corresponds fairly well to the acute gastritis described by the pathologist. The only way to make a positive diagnosis of acute gastritis is by biopsy. The specimen may be taken at the time of gastroscopy or by means of the blind gastric suction biopsy tube.

The symptoms most commonly associated consist of anorexia, epigastric distress and, occasionally, pain. Vomiting may occur. Diarrhea may be present because of associated enteritis.

Treatment consists of brief abstinence from food, followed by a bland, liquid diet. Subsequently, soft foods may be added. The course of the condition is generally self-limited.

CORROSIVE GASTRITIS. This form of gastritis most commonly occurs after the ingestion of acids, lyes or other corrosive substances. Corrosion results with inflammation and sloughing of the mucous membrane.

The symptoms of corrosive gastritis depend in part upon the corrosive agent. Epigastric burning and cramplike pain are usually present. Corrosion may occur in the mouth and esophagus with resultant dysphagia.

The initial treatment should be for the

shock which accompanies the gastritis. The stomach may be lavaged cautiously with water or specific antidotes. Treatment is not very satisfactory and stricture in the esophagus or pyloric stenosis may develop.

ACUTE INFECTIOUS GASTRITIS. This form of gastritis develops secondary to the influence of toxins or bacteria within the blood stream. It may be found in association with measles, scarlet fever, pneumonia or other infectious diseases.

It is manifested by nausea, anorexia and, occasionally, vomiting.

Food should be withheld until the patient can eat a bland diet. The course of the illness is self-limited.

PHLEGMONOUS GASTRITIS. Phlegmonous gastritis is characterized by inflammation of the gastric mucosa caused by streptococci, staphylococci or colon bacilli. Abscesses may be found within the gastric walls.

The symptoms are those of an acute infectious abdominal disease. Chills, abdominal pain and fever may all be observed.

Antibiotics should be used. If a localized abscess is present, it may have to be drained.

Chronic gastritis. This is a fairly common disease, the diagnosis of which has been made very loosely clinically, radiologically and even gastroscopically. A clinical diagnosis of gastritis has frequently been used as a sort of diagnostic wastebasket and, taken by itself, has little to substantiate it. A radiologic diagnosis of chronic gastritis based on thick folds and increased secretion of mucus is often of definite significance but should be confirmed by gastroscopy with biopsy. When the radiologist reports thick folds and suggests a diagnosis of hypertrophic gastritis, the question may arise as to the presence of lymphoma or even diffuse infiltrating carcinoma. In such instances, gastroscopic biopsy is exceedingly important.

Changes in the stomach may be found in association with other conditions. Inflammatory change may occur in association with primary gastric or duodenal disease and may render the differential diagnosis difficult. Gastritis may be associated with gastric carcinoma. It has been indicated that gastritis may be a precursor of carcinoma.

Gastritis may accompany either gastric or duodenal ulcer. It is more common with ulcers located in the stomach. Antral gastritis is extremely common, with ulcers located below the incisura angularis. Sometimes, on gastroscopic examination, one can visualize gastritis in the stomach in patients with a duodenal ulcer.

The Surgery of Peptic Ulcer

By JOEL W. BAKER, M.D.

JOEL W. BAKER is a Virginian who received his education at The University, as he and his fellow statesmen would say. He received his later surgical training in Washington where he is now chief of the surgical staff at the Virginia Mason Hospital and Chairman of The Mason Clinic in Seattle. He is an outstanding exponent of the teaching principle that surgery is the art of applying knowledge in the basic sciences to the patient.

INTRODUCTION

The high incidence of peptic ulcer in the general populace may explain the voluminous literature which has been devoted to considerations of the etiology and treatment of this disease. The multiple surgical procedures that have been sponsored for the control of ulcer attest the failure of present methods to supply an ideal solution. There is more recorded experimental and clinical research on the problem of peptic ulcer than on any other surgical subject.

An attempt has been made to review the principal considerations which mold the judgment of the surgeon as he is confronted

by this work and but a few of the more pertinent clinical reports, nevertheless if this policy were followed too rigidly, the challenge conveyed by some of the more recent and unconfirmed studies would then be lost and the fact might be overlooked that the final chapter in this problem has yet to be written. The surgeon cannot encounter this disease with complacency. The most popular procedures admittedly leave something to be desired both from the standpoint of untoward effects and sustained control of the ulcer diathesis. Nevertheless, for the surgeon individually to substitute procedures less established and less familiar in his hands, before they can be carefully evaluated in qualified centers, might indeed point to immature surgical judgment. Profound concepts must be based upon a thorough knowledge of the known factors in etiology, the supporting evidence from the experimental laboratory and, last

but not least, a conscientious follow up of one's own experience.

Be not the first by whom the new are tried,
Nor yet the last to lay the old aside.—Alexander Pope

PHYSIOLOGIC CONSIDERATIONS

A concept of the normal gastric physiology is a prerequisite to a study of the etiology of peptic ulcer. The stomach's primary function is the acid-peptic digestion of food and for this purpose the fundus and body (Fig. 39) are lined with parietal and chief cells secreting hydrochloric acid and pepsin.

LOCAL DEFENSE MECHANISM

1. Alkaline secretion neutralizes acid
2. Mucus layer protects surface
3. Food buffers the acid

Figure 39 The body and fundus of the stomach are lined by parietal and chief cells secreting hydrochloric acid and pepsin. A narrow rim of cardiac glands above and a 3-inch sleeve of antral pyloric glands below this acid-secreting area secrete a highly alkaline neutralizing and mucinous fluid, presumably as a protection to the very vulnerable esophagus on the one side and to the intestine on the other. This alkaline protection is reinforced in the second portion of the duodenum by the alkaline biliary and pancreatic secretions.

intractable cases, and those with complications, is surgery indicated. Medical treatment includes a bland diet and particularly antispasmodics. If obstruction, hematemesis, severe pain or complications exist, operation may be indicated.

ulation are surgically controllable, the cephalic phase through vagotomy and the gastric phase by antrectomy (i.e., resection of the distal one-third of the stomach). By varying the level of distal gastrectomy, different proportions of the acid-secreting target may be removed in addition to the hormone-secreting antrum. The quantitative relationship between the two phases of stimulation is interesting to contemplate and of practical importance in applying surgery to control ulcer. Unfortunately, the relative importance of the two is not convincingly established. Dragstedt attributes duodenal ulcer to a deranged neurogenic phase and, by contrast, attributes gastric ulcer to the hormonal phase. He and his coworkers believe duodenal ulcer should be best controlled by an attack on the neurogenic phase of stimulation (i.e., vagotomy) and that gastric ulcer should be more directly controlled by ablation of the gastric (hormone) phase (i.e., antrectomy). This approach to duodenal ulcer, however, cannot be reconciled entirely with some of the experimental work of Storer, Harkins and their associates. They have performed experiments on dogs with Heidenhain pouches to show that if the neurogenic avenue of stimulation is removed by vagotomy of the main stomach, there is an increase in secretion from the pouch, presumably due to a compensatory increase in the hormonal phase (Fig. 40). It is also

worthy of note that they found the gastric secretion to increase after gastroenterostomy. Evans, Dragstedt and their associates have since confirmed that there is increased gastric secretion of acid after vagotomy "when not accompanied by gastroenterostomy." It should also be mentioned that Lillehei, Lewis and Wangenstein have shown that where vagotomy is combined with gastroenterostomy, the quicker release of food from the stomach reduces the protective buffering effect of food during the delayed gastric phase of digestion, a phase that has been heightened, as just mentioned, by vagotomy, and also by gastroenterostomy. In the Sauvage pouch preparation, antrectomy was a more potent factor than vagotomy in reducing the incidence of marginal ulcer in the connecting jejunal loop.

In summary, then, the fundus and body of the stomach may be considered the secreting target and this target is normally stimulated to secretion at mealtime through neurogenic vagal impulses (cephalic phase) by a hormone secreted in the antrum (gastric phase) and by a hormone from the intestine (intestinal phase).

Experimentally Produced Ulcer. The experimental production of ulcer is pertinent to its etiology. However, the basic differences between the experimental animal, usually the dog, and man must be kept constantly in mind. In essence, all experimental

Figure 40 Graphic representation of free hydrochloric acid secretion (expressed in milliequivalents) from Heidenhain pouch of dog A-38 during control period (left) and collection periods after transthoracic section of vagus nerves to the main stomach (center) and subsequent gastrojejunostomy (right). (Schmitz, E. J., et al., The Effect of Vagotomy of the Main Stomach on Heidenhain Pouch Secretion. Surgical Forum, 1953)

These cells, either from an inherent immunity or otherwise, appear to be partially resistant to the digestive action of their own secretion, but the remainder of the gastrointestinal mucosa is more susceptible. As a possible protection from this acid, therefore, there is provided a narrow rim of cardiac glands above and a three-inch sleeve of antropylic glands below this acid-secreting area. These two barrier zones secrete a highly alkaline, neutralizing and mucinous fluid, presumably as a protection to the very vulnerable esophagus on the one side and to the intestine on the other. In addition, the cardiac sphincter and the angle of esophageal junction with the stomach mechanically protect the esophagus from the reflux of digestive juices. The distal protection is reinforced in the second portion of the duodenum by the daily flow of approximately 700 cc. each of alkaline bile and pancreatic juice. Barely does ulcer occur below this level of reinforcement.

The chemical neutralization is not the only local defense mechanism. A secreted layer of mucus mechanically protects the surface and, possibly most important of all, the food ingested at the height of acid secretion absorbs and buffers this acid. In the proximal duodenum a special layer of cells, referred to as Brunner's glands, secretes mucus and adds, therefore, to this protective surface coating. They are strategically located at the point toward which the jet stream of acid is directed. Since so much experimental work in ulcer has been done in dogs, it should be remarked that the occurrence of these protective glands is significantly less in the dog's duodenum than in the human.

To provide sufficient acid for digestion of the meal, experiments suggest there are three phases of gastric secretion, the cephalic, the gastric and the intestinal phase. Neurogenic impulses by way of the vagi, elicited by the sight or odor or taste of food, bring about the immediate hypersecretion of acid, the so-called *cephalic* or *neurogenic phase* of digestion. This conditioned reflex was described by Pavlov in 1900. The observations of Beaumont on his patient, Alex St. Martin, and the more recent observations of Wolf and Wolff in patients with gastroscopic windows demonstrated the profound influence on the appearance and function of the gastric mucosa effected by the changing emotional states mediated through the vagal nerves.

The second phase is induced by a hormone secreted by the gastric antrum and

called gastrin by Edkins in 1905. Gastrin is a histamine-like substance which reaches the corpus and fundus by way of the blood stream and in this delayed manner stimulates the target parietal cells to secretion, the so-called *gastric phase* of digestion. It is noteworthy that this phase is delayed, as contrasted with the immediate cephalic phase. Secretion of the hormone gastrin by the antrum is stimulated by local contact with food or by mechanical distention of the antrum. This is presumably through stimulation of the submucosal sensory receptors since the application of cocaine to the antral mucosa prevents the release of gastrin, even in the presence of food or distention. Dragstedt's studies have shown that hypersecretion of gastric juice may be induced through the endocrine influence of the antrum even after the antrum has been transplanted into the colon as a diverticulum. This secretion is abolished if the colon containing the antral diverticulum is excluded from gastrointestinal continuity and washed free of fecal material or food. Obstruction of this isolated segment, on the other hand, produced vigorous secretion, apparently by virtue of the peristaltic pressure alone.

There is a third phase of peptic digestion, referred to as the *intestinal phase*, which is stimulated by a hormone similar to but less powerful than gastrin. This hormone is assumed to be secreted by the mucous membrane of the small intestine when in contact with food. The character of this hormone has not been well defined. The subtle balance of physiologic checks and counter-checks effective in the control of secretion is suggested again by recent experimental work which shows the antrum to exert an inhibitory as well as a stimulating effect on acid secretion—a factor which may prove of surgical significance. This inhibitory effect is initiated by local contact of acid on the antrum. Whether this inhibitory influence of the antrum is mediated through a local effect which simply interferes with the secretion of gastrin or whether it is accomplished by the liberation from the antrum of a gastric inhibitory hormone is being currently explored. Likewise, the duodenum upon contact with hyperacid chyme may exert an inhibitory role on acid secretion.

These brief physiologic facts form the basis of both the medical and surgical treatment of peptic ulcer. They have been supported in the experimental laboratory. Both the cephalic and the gastric phases of stim-

fected possibly in a lowered local resistance on the part of the duodenal mucosa. This local susceptibility to erosion could be due to a variety of factors, including local vascular occlusive disease, or vascular spasm with local ischemia, portal venous hypertension, or to a number of as yet unexplained factors. This factor of local susceptibility must be added in order to explain the absence of ulcer in some patients with extremely high gastric acid secretion. In fact, some of the highest acid values have been found in the so-called neurasthenic patient without any objective evidence or history of ulcer. Finally, for years the emphasis has been placed on the local imbalance of acid secretion and its neutralization rather than on constitutional factors. However, the exacerbation of ulcer with personal stresses and the increased incidence of ulcer in periods of general emotional stress, as in times of economic depression and war, and the gradually increased incidence with the increased tempo of the atomic era—all these facts, combined with the emphasis in the last decade on the vagal influence—are making clinicians more conscious of the constitutional and psychogenic disturbances leading to this disease. The point to be emphasized is that the surgical attack remains a *local* approach for a constitutional disease and, therefore, leaves much to be desired.

ACUTE ULCERATION

Before the indications for surgery and the choice of surgical procedures for the control of chronic ulcer are considered, a warning should be sounded concerning *acute ero-*

rosions at least, to bend every effort to control upper gastrointestinal hemorrhage by adequate or continued blood transfusions before resorting to surgery—particularly if chronic ulcer has not or cannot be documented. Gastric resection for the acute erosion, instead of correcting a long-standing physiologic imbalance (as in chronic ulcer), sacrifices an important organ for a transient blemish—although granted this expediency is occasionally necessary in the last resort to save life. Massive hemorrhage from acute gastroduodenal ulceration without previous ulcer history has been reported in the immediate postoperative period of patients undergoing unrelated surgery. While these are examples of uncontrolled hemorrhage from acute, possibly “stress,” ulcer they must represent the exception rather than the rule. In general, if one treats the superficially bleeding erosions early, in the hospital, and gives continuous blood transfusions, they will usually stop bleeding—more often than will the penetrating calloused ulcer. The fact that acute erosions which may be quite superficial may also be associated with chronic ulcer must be borne in mind at emergency operation where the discovery of one bleeding point does not exclude others.

Likewise, in operations for acute perforations of the duodenum, simple closure is in order if the chronic ulcer diathesis cannot be documented. Such perforations may represent only an acute ulcer. The stomach should not be sacrificed for the transient lesion since the etiology of these acute erosions is not understood. Without a history of preceding chronicity it cannot be assumed that the ulcer will recur. Only for the perforation with calloused margin and a well-documented chronic history can primary gastric resection at the time of duodenal perforation be justified in the minds of those who approach the problem from a studied experience. The same is not true in gastric ulcer where primary resection of the perforated gastric ulcer is desirable, if not contraindicated by peritonitis. This differential is based upon the hazard of malignancy in the gastric ulcer and the greater difficulty in satisfactorily closing the perforation in the thicker gastric wall. For the calloused duodenal ulcer with a long documented history of chronic and recurring symptoms, primary resection at the time of perforation is thoroughly justified, provided, of course, generalized peritonitis does not make resection a prohibitive risk. Thorough peritoneal lav-

in gastroscopy occasionally see other than the characteristically punched-out, indurated, chronic ulcer. They may see, albeit more rarely, the small superficial erosions, varying in size, but usually small, and often multiple. These transient ulcers may bleed so massively as to require emergency resection or they may heal and not be demonstrated after bleeding ceases. It is known that similar acute ulcerations may also perforate. The acute ulceration seen in association with burn (Curling) or with stress may be but more advanced examples of erosions that may transiently occur and create such emergency problems. Because such erosions do bleed and can, therefore, confuse the picture, there is reason, in treating such

ulcer has been produced by altering the normal balance between acid secretion on the one hand and the defense mechanism on the other.

Mann and Williamson were able to produce ulcer consistently by deflecting the protective alkaline secretions of the duodenum, pancreas and liver into the terminal ileum, leaving thereby the jejunum anastomosed to the stomach and exposed without protection to the action of the gastric secretions (Fig. 41). The possible additional factor in this experiment of removing the inhibitory influence on acid secretion, which was shown by Sokolov in 1904 to reside in the duodenum, has been recalled recently by Brackney, Thal and Wangenstein. It is noteworthy that the marginal ulceration in the Mann-Williamson dog is reduced by vagotomy although total protection against ulcer is not afforded. Further proof of the protective importance of the pancreatic secretions is the work of Elman and Hartman who found that external deflection of the pancreatic secretions produced peptic ulcer in 100 per cent of dogs.* A seeming paradox to this, which present knowledge does not explain, is that Dragstedt found that in 300 animals maintained with suitable insulin replacement after total pancreatectomy (as contrasted with deflection of the pancreatic secretions), the incidence of ulcer was only 1.3 per cent. The influence of the rare alpha cell tumor of the pancreas on ulcer formation may be in some way related to these observations.

The second method of producing experimental ulcer was reported in 1940 by Code and Varco. Whereas heretofore experimental ulcer had been produced by deflecting the protective secretions, they produced experimental ulcer for the first time as a result of prolonged hypersecretion of acid. Where separately injected doses of histamine had failed to produce ulcer, the subcutaneous implantation of beeswax saturated with his-

* Parenthetically, and aside from experimentally produced ulcer, the protective importance of the alkaline biliary and pancreatic secretions is demonstrated clinically by the occasional chronic duodenal ulcer seen associated with carcinoma of the pancreas which has obstructed the biliary and pancreatic ducts and prevented these protective secretions from reaching the duodenum. I treated a patient who died from a massively bleeding marginal ulcer three years after a Whipple resection for carcinoma of the pancreas, presumably the result of erosion by unneutralized acid. The latter case illustrates the importance of considering a higher gastric resection in the Whipple operation done for cancer if the preoperative gastric acid secretion is in the higher range.

EXPERIMENTALLY PRODUCED ULCER Deflection of alkaline defense (Mann-Williamson, dog, 1923)

Fig. 41

tamine produced a sustained stimulation which resulted in ulcer. This experimental ulcer is not prevented by vagotomy because it is produced by stimulating the gastric phase of acid secretion rather than the cephalic phase.

Several other methods of producing ulcer have profound clinical significance. The ulcerating effect of retained unbuffered acid was demonstrated by Shay and his group. In fasting rats they ligated the pylorus, and multiple ulcers in the obstructed stomach consistently resulted. In a subsequent experiment, Harkins and Hooker showed that these rats are protected by vagotomy. The important buffering effect of food in the defense mechanism is demonstrated in the Fremont dog. The stomach is taken out of continuity, but the blood and nerve supply are preserved. In the absence of food in this isolated stomach, these dogs consistently develop ulcers but are protected by vagotomy as shown by Dragstedt.

ETIOLOGY OF PEPTIC ULCER

The work cited is but a fraction of the experimental workers' contributions to the understanding of the pathophysiology associated with chronic peptic ulcer. Nevertheless, at present, we must admit that the exact etiology of chronic benign ulcer is unknown, although obviously, two factors are quite generally accepted. These factors are (1) the hypersecretion of acid and pepsin, not alone in the normal manner at mealtime, but particularly the sustained secretion of this acid and enzyme in the interim between feedings, and (2) a constitutional factor re-

flected possibly in a lowered local resistance on the part of the duodenal mucosa. This local susceptibility to erosion could be due to a variety of factors, including local vascular occlusive disease, or vascular spasm with local ischemia, portal venous hypertension, or to a number of as yet unexplained factors. This factor of local susceptibility must be added in order to explain the absence of ulcer in some patients with extremely high gastric acid secretion. In fact, some of the highest acid values have been found in the so-called neurasthenic patient without any objective evidence or history of ulcer. Finally, for years the emphasis has been placed on the local imbalance of acid secretion and its neutralization rather than on constitutional factors. However, the exacerbation of ulcer with personal stresses and the increased incidence of ulcer in periods of general emotional stress, as in times of economic depression and war, and the gradually increased incidence with the increased tempo of the atomic era—all these facts, combined with the emphasis in the last decade on the vagal influence—are making clinicians more conscious of the constitutional and psychogenic disturbances leading to this disease. The point to be emphasized is that the surgical attack remains a *local* approach for a constitutional disease and, therefore, leaves much to be desired.

ACUTE ULCERATION

Before the indications for surgery and the choice of surgical procedures for the control of chronic ulcer are considered, a warning should be sounded concerning *acute erosions and their complications, and surgical implications* should be briefly reviewed.

Surgeons, pathologists and those interested in gastroscopy occasionally see other than the characteristically punched-out, indurated, chronic ulcer. They may see, albeit more rarely, the small superficial erosions, varying in size, but usually small, and often multiple. These transient ulcers may bleed so massively as to require emergency resection or they may heal and not be demonstrated after bleeding ceases. It is known that similar acute ulcerations may also perforate. The acute ulceration seen in association with burn (Curling) or with stress may be but more advanced examples of erosions that may transiently occur and create such emergency problems. Because such erosions do bleed and can, therefore, confuse the picture, there is reason, in treating such

erosions at least, to bend every effort to control upper gastrointestinal hemorrhage by adequate or continued blood transfusions before resorting to surgery—particularly if chronic ulcer has not or cannot be documented. Gastric resection for the acute erosion, instead of correcting a long-standing physiologic imbalance (as in chronic ulcer), sacrifices an important organ for a transient blemish—although granted this expediency is occasionally necessary in the last resort to save life. Massive hemorrhage from acute gastroduodenal ulceration without previous ulcer history has been reported in the immediate postoperative period of patients undergoing unrelated surgery. While these are examples of uncontrolled hemorrhage from acute, possibly "stress," ulcer they must represent the exception rather than the rule. In general, if one treats the superficially bleeding erosions early, in the hospital, and gives continuous blood transfusions, they will usually stop bleeding—more often than will the penetrating calloused ulcer. The fact that acute erosions which may be quite superficial may also be associated with chronic ulcer must be borne in mind at emergency operation where the discovery of one bleeding point does not exclude others.

Likewise, in operations for acute perforations of the duodenum, simple closure is in order if the chronic ulcer diathesis cannot be documented. Such perforations may represent only an acute ulcer. The stomach should not be sacrificed for the transient lesion since the etiology of these acute erosions is not understood. Without a history of preceding chronicity it cannot be assumed that the ulcer will recur. Only for the perforation with calloused margin and a well-documented chronic history can primary gastric resection at the time of duodenal perforation be justified in the minds of those who approach the problem from a studied experience. The same is not true in gastric ulcer where primary resection of the perforated gastric ulcer is desirable, if not contraindicated by peritonitis. This differential is based upon the hazard of malignancy in the gastric ulcer and the greater difficulty in satisfactorily closing the perforation in the thicker gastric wall. For the calloused duodenal ulcer with a long documented history of chronic and recurring symptoms, primary resection at the time of perforation is thoroughly justified, provided, of course, generalized peritonitis does not make resection a prohibitive risk. age with normal saline to prevent pocketing of foreign material is an important part of the operation for perforated viscus.

When primary resection is done either for perforation or hemorrhage in the patient with acute ulcer, the long-term result will not be gratifying and the "dividend" to the patient not nearly so apparent as in the patient who has suffered long from chronic ulcer. Should he develop any of the untoward sequelae of resection, they would prove particularly objectionable to him. It should also be pointed out that vagotomy has no established place in the control of these acute stress ulcers. Zubiran, Dragstedt and associates, for example, have shown that cortisone stimulation of gastric secretion occurs even after antrectomy and vagotomy. In dealing with the acute ulcer, one should look for the recent administration of corticoids and all factors conducive to stress. A relationship between acute erosion and chronic peptic ulcer has not been established. It is possible that acute ulcer may be the forerunner of chronic ulcer—at least in the vulnerable patient with hypersecretion of acid. It is known that chronic ulcers are generally limited in their occurrence to certain locations, that is, the first portion of the

duodenum, the antrum and the lesser curvature of the stomach and the lower esophagus—anatomic areas in which the mucosa is smooth and rather tightly adherent to the muscularis, in contradistinction to the fundus of the stomach where the mucosa hangs in folds and is loosely adherent to the underlying musculature (Fig 42). Ogilvie calls attention to this fact and suggests that if abrasions occur as a result of trauma, infections, dietetic indiscretions and the like in the fundus, where the mucous membrane is loose, the edges of the abrasion fall together as the stomach empties and it heals as rapidly as would a small burn on the eyelid, but if it occurs where the mucous membrane is fixed, the defect remains open as would a small burn on the bridge of the nose and acid digestion occurs before the abrasion can heal. In these, then, a chronic ulcer might result. The difference in significance in the acute and chronic ulcer is portrayed by Ogilvie when he says, "If we were able to inspect the lining of our whole alimentary canal with the constant scrutiny and minute attention that a girl devotes to studying her complexion, we should probably see that our inner surface, like our outer one, is constantly showing its blemishes."

ch. 1. 1925

sions are multiple and may occur anywhere and as a rule are of no significance, unless because of their location, combined with the patient's vulnerability, they become chronic or unless they massively bleed or perforate. The fact that on x-ray examination, duodenal ulcer is found approximately nine times as commonly as gastric ulcer, yet in autopsy subjects the incidence of ulceration in the duodenum and stomach is identical, lends weight to this philosophical hypothesis.

TREATMENT OF CHRONIC DUODENAL ULCER

The pathogenesis and, therefore, the etiology of chronic ulcer are better understood than those of acute ulcer. Suffice it to say that when the ulcer is situated in its more common location, that is, the first portion of the duodenum, a medical regimen should prove adequate in at least 80 per cent of cases. In most clinics, surgery is advised only because of the complications of ulcer or for those which prove chronically intractable to adequate medical treatment. Such treatment should encompass the principles of acid control, anticholinergic drugs, spacing buffering food in the stomach throughout the twenty-four hours, abstinence from the intemperate use of stimulants (nicotine, alcohol and coffee), combined with sedatives, mental and physical rest and recreation. A mistake that may be made in the

susceptible
erweight by
This is seen
case where

the patient comes late to surgery. The weight factor then adds to the risk as well as to the mechanical problems of surgery.

SELECTION OF THE PATIENT FOR SURGERY

From 30 to 75 per cent of gastric ulcers come to surgery because of the high recurrence rate when treated medically and because of the generally good results from surgical therapy, and particularly because resection is the only reliable way to exclude malignancy. By contrast, the ulcer in the duodenum, being unrelated to malignancy, requires surgical assistance in its management in percentages varying from only 10 to 20 per cent, the figures quoted from most medical centers. At The Mason Clinic, surgery has been applied in percentages varying from 10 to 15 per cent. In the last three years it has averaged 14 per cent. In other words, the duodenal ulcer is primarily a

medical and not a surgical disease. Elective surgery should be considered for the patient who has (1) intractable symptoms unrelieved by an adequate medical regimen, (2) unrelieved or recurring obstruction and (3) repeated hemorrhage.

Emergency surgery is required for acute perforation or uncontrolled hemorrhage. While surgery for intractability and obstruction is more often required in the fifth and sixth decades of life, it has been observed that the ulcer which first becomes manifest in the older patient and that which arises very early in life, as in the second decade, represent the more severe diathesis and are most prone to prove intractable. The old dictum of applying simple gastroenterostomy in the older patient with "burned-out ulcer scar" is no longer tenable. Gastroenterostomy per se is no longer considered adequate treatment for ulcer, certainly not for the limited number which justify surgical interference.

In selecting patients for surgery, the surgeon should deny acceptance for surgery, as long as possible, the asthenic, migrainous patient who is a finicky eater and who is underweight. This introvert finally exhausts his physician's patience and surgical assistance is sought. With any treatment there will be a high percentage of unsatisfactory results in these patients and an increased percentage of the dumping syndrome and other untoward sequelae after surgery. Such patients should not have surgery of any kind without prolonged observation on the part of the surgeon as well as the internist. To accept properly his responsibility, the surgeon must know firsthand the patient's history, habits in work and recreation, his worries, his reactions to possible marital or business problems, the inciting factors in the exacerbations of his symptoms and his cooperation, or lack of it, in following his physician's instructions. Before recommending surgery, he will be wise to discuss with the patient the possible untoward sequelae of surgery in a manner that does not necessarily plant the seed for introspective complaints but rather provides a protective understanding should they occur. Such sequelae will then be accepted, not as a result of a mistake on the part of the surgeon, but rather as an irreducible premium for control of the more crippling ulcer symptoms. By the same token, the internist or the patient's general physician should not be guilty of indifferent procrastination in advising surgery in the severe forms of the disease. Pos-

sibly the internist, in defining intractability, should place less reliance on the response of the patient to in-hospital treatment and more significance on the early relapse after hospital discharge when the patient resumes his occupation in the habitual environment in which he must continue to work. Unjustified and prolonged delay in advising surgery not only taxes the patient unfairly but also favors penetration of the ulcer, advanced fibrosis and a more extensive inflammatory reaction, factors which make more difficult the anastomosis or closure of the duodenal stump and thereby increase the technical hazards of surgery.

SELECTION OF THE SURGICAL PROCEDURE

When the refractory course or the complications of duodenal ulcer clearly justify surgery, the choice from a number of advocated surgical procedures places on trial the surgeon's judgment and his technical skill. As in medical management, all methods of surgical attack are directed at the reduction or subtotal elimination of gastric acid secretion, without which peptic erosion does not occur. This can be accomplished in varying degree by one or a combination of methods of altering gastric physiology (Fig. 43).

Basically these methods are, (1) vagotomy, thereby removing the cephalic phase of stimulation, (2) resection of the antrum, thereby removing the source of gastrin which is responsible for stimulating the delayed gastric phase of acid secretion, and which by experience and some experimental work might be interpreted to be the more influential of the two phases, and (3) resection of varying amounts of the acid-secreting

VARIETIES OF SURGICAL ATTACK FOR PEPTIC ULCER

Figure 43. See text for the combinations of the surgical attacks illustrated above.

body of the stomach, thereby reducing the acid-secreting "target" of parietal cells which can respond to any of the three avenues of stimulation. Simple drainage procedures, such as gastroenterostomy or pyloroplasty, are no longer considered adequate in their own right as a primary attack, although they are used as complementary procedures to the above.

DISTAL SUBTOTAL GASTRIC RESECTION

This operation began to supplant simple gastroenterostomy and pyloroplasty in the United States some thirty years ago, having been introduced from the European clinics by Berg and advocated by Strauss as early as 1917. At the time of its initial use, the physiologic rationale was not as well understood as now. It seemed a radical departure to subtotally remove an important organ for an ulcer no more than a centimeter in diameter. Its proponents were criticized and it was compared to the absurdity of amputating a leg to relieve a varicose ulcer. Contrast this attitude with the report in 1952 of the Committee of the American Gastroenterological Association which, after several years of study, reported 95 per cent satisfactory results following subtotal gastric resection.

The Physiologic Basis for the Procedure. Distal gastrectomy, in removing the antrum, ablates the delayed gastric hormonal (gastrin) phase of acid secretion and, at the same time, depending on the level of resection, removes a varying percentage of the acid-secreting target, or body of the stomach. Those using the method advocate from 60 to 80 per cent resection. It is essential to remove the entire antrum down to and beyond the pylorus, an accomplishment that may not be easy in the advanced penetrating ulcer. That the resection has extended beyond the pylorus into the duodenum, particularly on the posterior wall, should be insured by a recorded histologic confirmation.

Among those who advocate subtotal gastric resection there is a distinct difference of opinion as to the proximal extent of resection, that is, the amount of target remaining to be exposed to the stimulating vagal and other physiologic stimuli. The majority speak of a 75 per cent subtotal resection. Unfortunately, it is difficult to accurately determine the amount of stomach that is left. Priestley uses a formula developed by Heinrich, while Moore and Harkins have developed a method utilizing planimetry

and weight. This is designed to estimate more accurately the percentage of stomach that is left. Hart prefers a 60 to 65 per cent resection, preserving thereby more gastric capacity and presumably better postoperative nutrition. He believes that clinicians should be more liberal in advising surgery for the patient who cannot live a reasonably satisfactory life with his ulcer, but that surgeons should be more conservative in this primary resection, reserving the more radical resection for the few who suffer recurrence. He believes that all surgical patients should not be "inflicted" with a high subtotal resection and the increased risk of undernutrition and "dumping" in order to protect better the few who are apt to develop recurrent ulcer. It does seem reasonably established that the higher the resection, the lower the incidence of recurrent ulcer, but that the higher resection may result in a greater percentage of the "small stomach syndrome" and "dumping."

After gastric resection, the *restoration of gastrointestinal continuity* presents a separate consideration. Whereas resection is designed to control ulcer, by contrast the various methods of re-establishing continuity are aimed at reducing to a minimum the untoward sequelae therefrom, although some also claim enhancement of ulcer control by the particular anastomosis of their choice. Essentially the choice is between an end-to-end gastroduodenostomy (Billroth I), on the one hand, and an end-to-side gastrojejunostomy (Billroth II), on the other. Certainly the accomplished surgeon will be versed in the variations of both methods so that he will not be forced to stretch a single method beyond its reasonable limitations.

Gastrojejunostomy. After resection for duodenal ulcer, gastrojejunostomy (Fig. 44) remains the most widely used anastomosis. This is for two reasons, in the first place, it can be accomplished without tension on the suture line regardless of the height of the

METHODS OF ANASTOMOSIS AFTER PARTIAL OR SUBTOTAL GASTRECTOMY

Fig 44

resection and, in the second place, the deformed duodenum may not lend itself well to anastomosis and the surgeon is compelled to use the jejunum. In those clinics where surgery for ulcer is restricted to the more complicated cases, the surgeon has to deal with a relatively large number of advanced deformities of the duodenum. He may, therefore, for technical reasons, have to forego the physiologic and mechanical advantage of the Billroth I gastroduodenostomy in many of these. Actually, in the larger series of followed cases reported, the difference in untoward sequelae for the two methods has not been impressive, and Ordahl and his associates surprisingly found a higher incidence of recurrent ulcer to follow the Billroth I than the Polya anastomosis where the same extent of gastric resection was done for duodenal ulcer.

In anastomosing the end of the gastric stump to the jejunum, the entire cross section of the stump may be anastomosed (Polya 1911 and Moynihan 1923) or the lesser curvature side may be closed using a lesser width for anastomosis (von Eselsberg 1889 and Hofmeister 1896). For the higher lesser curvature ulcer, there are technical advantages in closing rather than anastomosing the lesser curvature. The functioning diameter of the anastomosis will depend upon the diameter of the distal jejunal loop and it has been pointed out by some that a larger anastomosis could enhance the chance for "dumping" into the proximal loop. Prohaska, Govosts and Kirsteins have suggested that stomal dysfunction following subtotal gastrectomy is caused, not by stomal edema, but rather by an atonic gastric pouch in which the efferent outlet is placed above the afferent inlet. It was found that this combination occurred more frequently in the "antiperistaltic" end-to-end gastrojejunostomy in which the distal loop of jejunum is placed in continuity with the lesser curvature of the stomach. If a retrocolic anastomosis is made, proponents point out two advantages. A shorter loop of jejunum (1 to 3 inches distal to Treitz ligament) can be used and one avoids the mechanical disadvantages of pulling a longer loop of jejunum around in front of a heavy greater omentum in the obese patient. Some would meet this last objection by removing the greater omentum in the extremely obese. The shorter the jejunal loop employed, the higher will be the concentration of alkaline, pancreatic and biliary secretions which bathe and protect the anastomosis. That a longer loop may

predispose to recurrent ulcer has been explained by Kiriluk and Merendino on this basis rather than on the basis of an increasing inherent vulnerability of the more distal jejunal mucosa. The posterior anastomosis is technically a little more difficult in that the margins of the surgical aperture in the transverse mesocolon (which should always be made to the left of the midcolic vessels) must be sutured in a collar-like manner to the stomach above the anastomosis. If this is not done, the aperture could descend and strangle the anastomosis and create obstruction to either or both the afferent and efferent loops. The anterior anastomosis may be preferable in a secondary resection where the transverse mesocolon is indurated from marginal ulceration or where its vascular arcades are not sufficiently wide to permit an adequate opening. In either the antecolic or retrocolic anastomosis, one should try to see that the anastomosis lies transversely without tension and that the aperture of the *afferent loop is not lower than the efferent loop*. Some would insist that the proximal or afferent loop be anastomosed to the lesser curvature and some prefer this in the postcolic anastomosis. However, in the antecolic anastomosis this may at times be reversed and the proximal loop be anastomosed to the greater curvature, if by so doing it seems to assure a better transverse position without tension.

Gastroduodenostomy. The Billroth I (1881), or variations thereof, is used by the majority of surgeons following resection of benign gastric ulcer because (1) a lesser resection is usually performed for gastric ulcer and (2) the uninvolved duodenum lends itself well to anastomosis. There are staunch advocates of the method and it is used also after resection for duodenal ulcer. When the deformed stump does not permit end-to-end anastomosis, an end-to-side gastroduodenostomy (von Haber 1922 and Finney 1923) is employed (Fig. 44). Experimentally, the Harkins group found restoration by gastrojejunostomy following partial gastrectomy to result in a higher level of gastric secretory activity than after gastroduodenostomy. Marginal ulceration in the animals occurred earlier and oftener after gastrojejunostomy. There is experimental evidence suggesting that excess acid in the duodenum acts as an inhibitory influence on the further secretion of acid by the stomach, probably through a hormone influence. This had been suggested by Sokolov as early as 1904. The work of Harkins' group confirmed

that of Dragstedt's group that this protective influence by contrast is lost after gastro-jejunostomy. Everson has shown, in the experimental animal at least, that the assimilation of fat and protein is reduced less after the Billroth I than after the Billroth II procedures. Also, it is pointed out that the duodenal anastomosis is closer to the protective alkaline reinforcement of pancreatic and biliary secretions and that the duodenum, as contrasted to the jejunum, is guarded by Brunner's glands which secrete additional alkali and a protective mucus.

Mechanically, of course, an end-to-end anastomosis approaches the normal more than an end-to-side. There is one less suture line, the lower compartment of the abdomen is not soiled during the anastomosis and one does not have to deal with the problems of the greater omentum and the mesentery of the colon. These advantages might be considered overwhelmingly in favor of gastro-duodenostomy. However, in actual clinical practice the follow-up results, while hard to evaluate because of the many variables introduced, nonetheless fail to convince many authorities either as to its advantage in ulcer control or in reduction of untoward sequelae. They would warn against overextending the indications for its use, particularly where technical hazards make the anastomosis difficult. Goligher, Moir and Wrigley found the ulcer recurrence rate in a three year follow-up rose from 2 to 17 per cent when the Billroth I was substituted for the Polya procedure, a 75 per cent resection having been done in each series.⁴ Ordahl, Ross and Baker found the Billroth I to be preferable for gastric ulcer but to be followed by a 28.6 per cent incidence of recurrent ulcer when used for duodenal ulcer. On the other hand, in a larger series of cases, Harkins and Nyhus reported a recurrence rate (proved and unproved cases) of 3.5 per cent. While it is true that technically if one frees the entire greater curvature and divides the left gastric artery and mobilizes the duodenum, the anastomosis can be accomplished in most cases without tension in the hands of the more expert, the less experienced may be ill advised to attempt it. There does not seem to be sufficient proved advantage in the Billroth I anastomosis to justify stretching the reasonable indications for its use. To do so could tempt one to do an inadequate resection of the stomach or to establish the anastomosis under tension.

The ideal end result after gastric resection of the type of anastomosis,

is a small stomach having a capacity of a pint or less, with low acid secretion limited to the mealtime and a gastric emptying time of about one-half an hour.

VAGOTOMY

The transmission by way of the vagus nerves of influences important to gastric secretion was pointed out by Rokitsansky a hundred years ago. Vagotomy as a modality of surgical treatment for peptic ulcer was introduced by Dragstedt and Owens in 1913. Heretofore, the attack on ulcer had been a local one. Vagotomy, by contrast, takes into account the psychosomatic factor in the etiology of ulcer in that it blocks the neurogenic avenues of stimulating gastric secretion and accomplishes more completely the purpose for which the anticholinergic drugs have long been used. Furthermore, it was shown that vagotomy, presumably on the basis of acid reduction, relieved the pain of ulcer. It had the advantage of not sacrificing the volume capacity of the stomach. But, on the other hand, it may be argued that it affords no direct attack for the complications of ulcer (perforation, obstruction and hemorrhage). It is to be remembered that in most centers it is these complications that constitute the chief indication for surgery. In general, it may be said that vagotomy alone is no longer considered an adequate primary attack for primary ulcer.

One of the more undisputed indications for vagotomy per se is secondary gastro-jejunal ulceration. The Committee of the American Gastroenterological Association found a favorable response from vagotomy in 81 per cent of patients with recurrent ulcer following simple gastroenterostomy and in 72 per cent with ulcer following gastric resection. Walters, Chance and Berkson reported similar results. Whether one should be content in applying vagotomy alone for recurrent ulcer may require individualization. Healing of the very indurated ulcer may be prevented by its scar and resection of the ulcer should be done in addition to the vagotomy. One should also search for the cause of previous failure of ulcer control, such as a retained portion of the gastric antrum, inadequate resection of the body of the stomach, a too-long jejunal loop or a poor placement of the gastroenterostomy. Any of these deficiencies will require correction in addition to vagotomy. In recurrent ulcer a search for an islet alpha cell tumor of the pancreas should also be made.

VAGOTOMY COMBINED WITH GASTROJEJUNOSTOMY OR PYLOROPLASTY

Because vagotomy impairs the motor function of the stomach and because the healing of an active ulcer after vagotomy has also resulted in obstructive retention, it is now considered best to add either gastroenterostomy or pyloroplasty to the vagotomy in order to produce better gastric emptying. But it was pointed out by Lillehei that by this combination the stomach is left unprotected by food during the delayed gastric phase of hypersecretion. Two individually inadequate procedures, it may be argued, are thus combined and the patient exposed to the untoward effects of each, protracted diarrhea being the most objectionable. There is no justification to add vagotomy to an adequate 75 per cent gastric resection because this has not afforded additional protection, according to the follow-up report of the Committee of the American Gastroenterological Association.

However, it should be mentioned again that Dragstedt has emphasized the possible specificity of vagotomy for the control of duodenal ulcer. His experimental work suggests to him that duodenal ulcer results from the neurogenic phase of hypersecretion, in contrast to gastric ulcer which he believes

should be more specifically controlled by an attack on the hormonal phase of hypersecretion. It would seem, however, that some of the earlier advocates have forsaken gastrojejunostomy in combination with vagotomy and have substituted antrectomy and gastroduodenostomy as an auxiliary procedure to vagotomy. The generally accepted situation in which a number of surgeons prefer simple gastroenterostomy and vagotomy arises when there is a penetrating duodenal ulcer or a markedly deformed duodenum which makes pylorotomy and a Billroth I gastroduodenostomy difficult or hazardous to accomplish. The incidence of recurrent ulcer is approximately twice that following a two-thirds gastric resection, being about 10 per cent (5 per cent proved and 5 per cent suspected). However, the mortality in vagotomy and gastroenterostomy when applied to the difficult penetrating ulcer would be appreciably less than that following resection of the ulcer.

Technical Considerations. Vagotomy may be accomplished supradiaphragmatically by way of a transthoracic approach or subdiaphragmatically by way of an abdominal approach. It is ineffective unless all of the vagal fibers are divided. The original 10 per cent failure to accomplish complete vagotomy may be reduced with greater experi-

ence of the surgeon and a better appreciation of the varying anatomic course of the vagal nerve fibers. In performing the concomitant gastrojejunostomy, Dragstedt has stated that it should be placed in the antrum within 4 or 5 cm. of the pylorus. Crile has emphasized placing it distally in the dependent portion of the stomach and warns against an inversion by multiple layers of suture (Fig. 45).

ANTRECTOMY COMBINED WITH VAGOTOMY

Physiologic and Surgical Considerations.

According to present knowledge, if the entire antrum of the stomach is resected, the source of the hormone gastrin would be thereby removed and the gastric hormonal phase of gastric hypersecretion would be eliminated. If, in addition, both vagus nerves are divided, the neurogenic or cephalic phase of secretion is also destroyed, leaving only the intestinal hormone (third phase) to stimulate the remaining gastric fundus to secretion. This should, theoretically at least, accomplish total or near total achlorhydria and peptic digestion cannot occur in the absence of hydrochloric acid. According to present concepts this should, therefore, accomplish near perfect control of the ulcer diathesis. It should be technically easier to perform than is a high subtotal gastric resection, particularly in the fat or barrel-chested individual with a small stomach situated high beneath the diaphragm. By removing only the antrum, a greater gastric capacity is retained and Zollinger believes this an important advantage in the patient who is preoperatively below normal weight.

The chief objection to this combination is the fact that it has not as yet had sufficiently wide application and patients have not been followed long enough for dependable evaluation. Many surgeons prefer to await the results of longer study from the large, qualified experimental centers before adopting this method. Subtotal gastrectomy by contrast has been used in this country for thirty years and, while the results are by no means perfect, it has afforded approximately 95 per cent good results. It remains one of the more satisfactory abdominal operations. Whether the resulting total achlorhydria of vagotomy and antrectomy is completely desirable is a question also raised by some and, in this connection, the association of polyps and pernicious anemia with achlorhydria has been cited. A diminished absorption of fat has been found to follow vagotomy.

The vagus nerves supply not only the stomach, but also the entire small intestine, at least part of the colon, the liver and the pancreas. Whether total vagotomy at the diaphragmatic level for benign peptic ulcer, therefore, will in the long-term follow-up prove justifiable is still held by some as open to question.

Furthermore, in the severely penetrating duodenal ulcer or in the deformed duodenum a Billroth I gastroduodenostomy may not be feasible and then the antrectomy must be completed by gastrojejunostomy, or else the antrectomy substituted by simple gastroenterostomy. Actually, the results in the few centers which have reported on this procedure have uniformly shown an absence of recurrent ulcer, except in a few instances where vagotomy was incomplete. Most reports speak of a "50 per cent" or "limited" gastrectomy in combination with the vagotomy rather than limiting the resection strictly to antrectomy. This should be borne in mind by those adopting the method. In general, the antrum can be recognized grossly by its smooth surface and adherent submucosa in contradistinction to the loose redundant rugal folds of the fundus (Fig. 42). It requires a resection of from 40 to 50 per cent to insure complete removal of the antrum. Since the antral cells extend up the lesser curvature, the resection should be higher on the lesser curvature side. The untoward effects have been about the same as following the high subtotal gastrectomy. In any surgical approach depending on vagotomy alone or in combination, there is the hazard of failure from incomplete vagotomy. This was found to be as high as 10 per cent in the earlier series.

MISCELLANEOUS SURGICAL MODALITIES

Numerous combinations of surgical procedures for duodenal ulcer have been applied or recommended and some of these are currently being studied in centers which by virtue of their organized follow-up ulcer clinics are in a position to supply an eventual evaluation. Wangensteen has forsaken his so-called tubular gastric resection in which the fundus and greater curvature were resected longitudinally and the lesser curvature preserved as a reconstructed tube (Fig. 46). This approach was designed to resect all of the acid-secreting target. He now is employing a "segmental" three-quarter mid-gastric sleeve resection with anastomosis between the remaining small fundic pouch and the antrum, combined with a Heineke-Mi-

VAGOTOMY COMBINED WITH GASTROJEJUNOSTOMY OR PYLOROPLASTY

Because vagotomy impairs the motor function of the stomach and because the healing of an active ulcer after vagotomy has also resulted in obstructive retention, it is now considered best to add either gastroenterostomy or pyloroplasty to the vagotomy in order to produce better gastric emptying. But it was pointed out by Lillehei that by this combination the stomach is left unprotected by food during the delayed gastric phase of hypersecretion. Two individually inadequate procedures, it may be argued, are thus combined and the patient exposed to the untoward effects of each, protracted diarrhea being the most objectionable. There is no justification to add vagotomy to an adequate 75 per cent gastric resection because this has not afforded additional protection, according to the follow-up report of the Committee of the American Gastroenterological Association.

However, it should be mentioned again that Dragstedt has emphasized the possible specificity of vagotomy for the control of duodenal ulcer. His experimental work suggests to him that duodenal ulcer results from the neurogenic phase of hypersecretion, in contrast to gastric ulcer which he believes

should be more specifically controlled by an attack on the hormonal phase of hypersecretion. It would seem, however, that some of the earlier advocates have forsaken gastrojejunostomy in combination with vagotomy and have substituted antrectomy and gastroduodenostomy as an auxiliary procedure to vagotomy. The generally accepted situation in which a number of surgeons prefer simple gastroenterostomy and vagotomy arises when there is a penetrating duodenal ulcer or a markedly deformed duodenum which makes pylorectomy and a Billroth I gastroduodenostomy difficult or hazardous to accomplish. The incidence of recurrent ulcer is approximately twice that following a two-thirds gastric resection, being about 10 per cent (5 per cent proved and 5 per cent suspected). However, the mortality in vagotomy and gastroenterostomy when applied to the difficult penetrating ulcer would be appreciably less than that following resection of the ulcer.

Technical Considerations. Vagotomy may be accomplished supradiaphragmatically by way of a transthoracic approach or subdiaphragmatically by way of an abdominal approach. It is ineffective unless all of the vagal fibers are divided. The original 10 per cent failure to accomplish complete vagotomy may be reduced with greater experi-

ence of the surgeon and a better appreciation of the varying anatomic course of the vagal nerve fibers. In performing the concomitant gastrojejunostomy, Dragstedt has stated that it should be placed in the antrum within 4 or 5 cm. of the pylorus. Crile has emphasized placing it distally in the dependent portion of the stomach and warns against an inversion by multiple layers of suture (Fig. 45).

ANTRECTOMY COMBINED WITH VAGOTOMY

Physiologic and Surgical Considerations.

According to present knowledge, if the entire antrum of the stomach is resected, the source of the hormone gastrin would be thereby removed and the gastric hormonal phase of gastric hypersecretion would be eliminated. If, in addition, both vagus nerves are divided, the neurogenic or cephalic phase of secretion is also destroyed, leaving only the intestinal hormone (third phase) to stimulate the remaining gastric fundus to secretion. This should, theoretically at least, accomplish total or near total achlorhydria and peptic digestion cannot occur in the absence of hydrochloric acid. According to present concepts this should, therefore, accomplish near perfect control of the ulcer diathesis. It should be technically easier to perform than is a high subtotal gastric resection, particularly in the fat or barrel-chested individual with a small stomach situated high beneath the diaphragm. By removing only the antrum, a greater gastric capacity is retained and Zollinger believes this an important advantage in the patient who is preoperatively below normal weight.

The chief objection to this combination is the fact that it has not as yet had sufficiently wide application and patients have not been followed long enough for dependable evaluation. Many surgeons prefer to await the results of longer study from the large, qualified experimental centers before adopting this method. Subtotal gastrectomy by contrast has been used in this country for thirty years and, while the results are by no means perfect, it has afforded approximately 95 per cent good results. It remains one of the more satisfactory abdominal operations. Whether the resulting total achlorhydria of vagotomy and antrectomy is completely desirable is a question also raised by some and, in this connection, the association of polyps and pernicious anemia with achlorhydria has been cited. A diminished absorption of fat has been found to follow vagotomy.

The vagus nerves supply not only the stomach, but also the entire small intestine, at least part of the colon, the liver and the pancreas. Whether total vagotomy at the diaphragmatic level for benign peptic ulcer, therefore, will in the long-term follow-up prove justifiable is still held by some as open to question.

Furthermore, in the severely penetrating duodenal ulcer or in the deformed duodenum a Billroth I gastroduodenostomy may not be feasible and then the antrectomy must be completed by gastrojejunostomy, or else the antrectomy substituted by simple gastroenterostomy. Actually, the results in the few centers which have reported on this procedure have uniformly shown an absence of recurrent ulcer, except in a few instances where vagotomy was incomplete. Most reports speak of a "50 per cent" or "limited" gastrectomy in combination with the vagotomy rather than limiting the resection strictly to antrectomy. This should be borne in mind by those adopting the method. In general, the antrum can be recognized grossly by its smooth surface and adherent submucosa in contradistinction to the loose redundant rugal folds of the fundus (Fig. 42). It requires a resection of from 40 to 50 per cent to insure complete removal of the antrum. Since the antral cells extend up the lesser curvature, the resection should be higher on the lesser curvature side. The untoward effects have been about the same as following the high subtotal gastrectomy. In any surgical approach depending on vagotomy alone or in combination, there is the hazard of failure from incomplete vagotomy. This was found to be as high as 10 per cent in the earlier series.

MISCELLANEOUS SURGICAL MODALITIES

Numerous combinations of surgical procedures for duodenal ulcer have been applied or recommended and some of these are currently being studied in centers which by virtue of their organized follow-up ulcer clinics are in a position to supply an eventual evaluation. Wangenstein has forsaken his so-called tubular gastric resection in which the fundus and greater curvature were resected longitudinally and the lesser curvature preserved as a reconstructed tube (Fig. 46). This approach was designed to resect all of the acid-secreting target. He now is employing a "segmental" three-quarter mid-gastric sleeve resection with anastomosis between the remaining small fundic pouch and the antrum, combined with a Heineke-Mi-

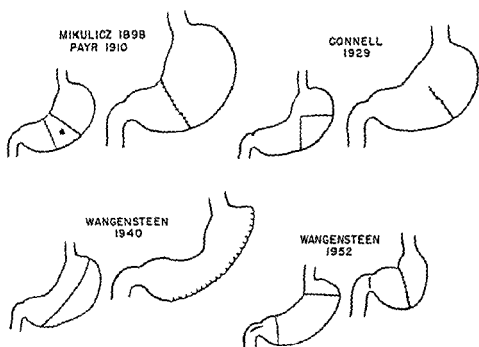

Figure 46 Miscellaneous surgical modalities.

Figure 47 Miscellaneous surgical exclusion operations.

kulicz pyloroplasty (Fig. 45). By this method the greater portion of the acid-secreting body of the stomach and a part of the hormone-secreting antrum are removed and at the same time some of the antrum is intentionally left. Wangenstein and Berne, who has used a similar surgical approach, have suggested that any remaining acid secretion will thereby contact the remaining antrum and invoke the inhibitory function of the latter against further acid secretion. Any antianemic factor of the antrum is likewise preserved as well as its protective mucus and alkaline secretions. Waddell and Bartlett have revived antral exclusion and combined it with vagotomy, presumably expecting the latter to protect against the high incidence of recurrent ulcer seen in former years when antral exclusion was suggested by Devine (Fig. 47) and adopted by others as a technical solution for the difficult penetrating duodenal or pyloric ulcer. Since it requires a long period to evaluate the effective ulcer control and untoward effects of any surgical procedure, the majority of surgeons may prefer to await longer follow-up reports before applying these newer methods.

FACTORS IN THE SELECTION OF THE SURGICAL PROCEDURE

A follow-up study of results has shown that each surgical procedure so far applied to duodenal ulcer leaves something to be desired in some patients both from the standpoint of failure to control ulcer and because of untoward sequelae. Even those who are partial to a particular procedure may at times substitute another procedure either for (1) *technical reasons* or (2) because of certain *clinical considerations*. In the latter category, Zollinger and Smithwick are among those who, for the underweight patient, would prefer to preserve more gastric capacity. Therefore, instead of applying subtotal gastric resection, they would apply either vagotomy with gastroenterostomy, or vagotomy with antrectomy and a Billroth I anastomosis. Zollinger observed that whereas the majority of his patients who were overweight prior to surgery would hold their ideal weight after an extensive gastric resection of the Hofmeister type, this was not true for the majority of the patients who were below their ideal weight at the time of operation, whether or not they had at one time been above this weight. For the latter, he would not do an extensive resection. For those *described* to be unusually sus-

ceptible to psychogenic influences, the addition of vagotomy may take on added importance. Those favoring gastric resection may vary the extent of the resection from 60 per cent to 80 per cent, depending upon the adjudged severity of the disease, preserving a greater gastric capacity in the milder cases.

Bruce, adopting Kay's method of measuring quantitatively gastric acid in response to histamine, has attempted to evaluate the severity of the ulcer diathesis and to fashion individually the type of surgical procedure to be applied in each case. Kay found that a dose of 0.04 mg. of histamine per kg. of body weight will elicit the maximum secretory response from the entire population of parietal cells and that this response varies widely with different patients with ulcer. But, since it is a maximum response, it is constant on repeated tests for the same individual. Greater doses of histamine beyond that stated did not further affect secretion. The patient is protected from side effects of the large doses of histamine by antihistamine drugs, and by gastric tube the secretion of acid is measured for the forty-five-minute period after histamine is given. Bruce has considered the test as a measure of the severity of the ulcer diathesis and, on histologic examination of stomachs resected for ulcer, he has found a correspondingly greater density of parietal cells per unit of mucosa in those with the greater secretory response. By means of the test he divides the patients requiring surgery for duodenal ulcer into three clinical groups. For those with only moderate elevation of secretion he would apply vagotomy and gastroenterostomy, particularly where technical hazards or impaired risk argues for this technically easier procedure. For those with more marked elevation of secretion he would apply 60 per cent subtotal resection, and for those with very high secretion, 75 per cent resection plus vagotomy. He finds that the 60 per cent distal resection will reduce by 45 per cent the milliequivalent level of preoperative secretion. He expects by surgery to reduce the maximum secretion to within the range found in normal patients without ulcer.

In the man, *technical problems* become the more common reason for altering the surgical attack. Priestley refers to the overweight, barrel-chested patient with a well-rounded belly and a firm, thick, abdominal wall, who commonly has a small stomach situated high and deep in the abdomen in a virtually transverse direction. He points

Figure 48 A, Method of gastric resection for the deformed duodenum with ulcer perforating into the pancreas. The duodenum is transected distal to the pylorus without regard to the large, perforating ulcer which is bordered by dense scar and thickened pancreatic capsule. A frozen section is made from the posterior distal end of the specimen to prove duodenal mucosa and to insure for the record that all of the antrum has been removed. B, Fine interrupted silk is used to approximate the seromuscular layer of the anterior duodenal wall to the thickened pancreatic capsule and to the proximal margin of the ulcer. The mucosal edge is thereby inverted without suture (Baker, J W, Boyd, R S, and Foster, R A. Ann Surg., vol 142)

out that in such a patient an adequately high gastric resection is more difficult. The greater omentum and the mesenteries infiltrated with fat add to the hazards of any of the Billroth II modifications. Such patients, of course, should be reduced in weight before surgery. Unfortunately, they have such intractable symptoms that their ulcer management of increased milk and cream intake, granted it has been prolonged too long, has added to their weight. In such instances, some surgeons would do an antrectomy and vagotomy, the lesser resection with a Billroth I anastomosis being much easier than a higher resection.

Resection of the peptic ulcer which has perforated through the duodenum into the pancreas is fraught with technical hazards, predisposing to increased morbidity and mortality. The danger to the common bile duct, the pancreas and its ducts, and an insecure duodenal closure have influenced some stanch resectionists to substitute other measures for gastrectomy. In these patients, vagotomy and gastroenterostomy, antral exclusion and vagotomy or a two-stage gastric resection have been employed. The technical hazards can be overcome by excluding the ulcer into the duodenal stump. This can be accom-

plished without sacrificing the physiologic requirements embodied in resection (Fig. 48). The importance of proving histologically that the resection has been carried beyond the pylorus to insure removal of all of the antrum must be stressed. The method is not applicable in emergency resections done to control bleeding from the duodenal ulcer. Such exclusion was first suggested by Nissen and is to be distinguished from the antral exclusion of Devine (Fig 47), which has proved unsuccessful in ulcer control, and from the Bancroft or Finsterer technique in which the antral mucosa is rimmed out but the seromuscular coats are preserved for closure. This latter technique meets the physiologic obligation of removing the antrum, but is less accurate in removing all of the antral mucosa. Furthermore, it is technically more difficult to accomplish with neatness and safety. Baker compared a followed series of 122 patients, in which resection was accomplished by leaving the ulcer and excluding it into the duodenum, with 156 patients, in whom the ulcer was resected. He found the mortality in the excluded group to be 0.8 per cent (one patient) and in the resected group to be 1.9 per cent (three patients).

recurrent ulcers suspected in each series, only one in each series requiring secondary surgery.

Duodenostomy. In occasional instances the surgeon may have elected to resect the duodenal ulcer only to find, as the resection progresses, an unanticipated difficulty which prevents a convincingly secure closure of the duodenal stump. In order to convert a possible leak into a controlled fistula, the duodenal stump may be closed around a small soft rubber catheter which is brought through the abdominal wall as a duodenostomy. It is best to reinforce this closure of the stump by tacking the adjacent omentum over the exit of the tube. Most surgeons leave either a cigarette or suction drain in the subhepatic space adjacent to the duodenostomy catheter. Welch first called attention to the advantage and safety of duodenostomy after gastric resection and later reported ten cases in which the procedure was used without a death. He prefers to combine the duodenostomy with a double-catheter jejunostomy after the manner of Allen and Donaldson. Priestley, Ross and Warren, Hoerr and Caudell, Garrison and Lee are among those who endorse the use of duodenostomy for the rare instance in which closure of the duodenal stump presents a problem. The tube is clamped about the eighth day and removed on the tenth day, the drain site usually healing promptly thereafter. Stomal obstruction will require leaving the tube longer. Measured replacement of the fluid and electrolyte loss is obviously important. Complications include leakage around the duodenal catheter, an anastomotic ulcer in the immediate post-operative period presumed due to loss of the protective alkaline pancreatic and biliary secretions, and prolonged drainage from the sinus tract.

It should be remembered that a temporary "duodenostomy" may be more simply accomplished by placing an indwelling nasogastric tube at the time of the gastrojejunostomy into the proximal loop well beyond Treitz ligament. In such instances, additional holes may be cut in the tube to simultaneously suction the remaining stomach. The disadvantage of this method is the discomfort of the patient and the other complications of nasogastric tubes which limit their usefulness beyond one or two days post-operatively.

If the dilemma which makes duodenostomy advisable can be anticipated before irreversible resection of the ulcer has been

joined, it is obviously better and safer to substitute either a two-stage resection or vagotomy combined with gastrojejunostomy.

ULCER COMPLICATED BY OBSTRUCTION

Gastric retention may complicate pyloric or duodenal ulcer as a result of either (1) spasm, (2) edema or (3) organic deformity. This may be discovered only upon roentgenologic examination or it may be clinically evident because of vomiting. Retention of gastric acid prevents healing of the ulcer and may become associated with secondary gastric erosions. Persistent vomiting may lead to hypochloremic alkalosis through the loss of electrolytes—particularly chloride ions—and prolonged vomiting to hypokalemia. The state of nutrition may suffer and total blood volume may be reduced.

The treatment is directed at gastric decompression either by continuous gastric suction or by aspiration of the stomach night and morning, combined with a liquid diet. To be emphasized is the fact that anticholinergic drugs are contraindicated because they serve to increase the retention. Usually, forty-eight hours of continuous suction will relieve any superimposed edema and the subsequent plotting of twenty-four hourly oral intake versus gastric output will determine the degree of any persisting organic obstruction. During this trial period, serum electrolyte determinations should be made and deficiencies gradually corrected. Unrelieved obstruction is an indication for surgery. However, surgery should not be undertaken until the superimposed edema and gastric distention has been relieved by several days of suction and until the electrolyte imbalance has been at least partially restored. Surgery done before this is accomplished may result in hazardous resection and insecure anastomosis. An anastomosis may become smaller than desired when elimination of edema and restoration of gastric tone are accomplished after rather than before operation. On the other hand, in the face of unrelenting obstruction, gastric suction and parenteral support should not be pursued more than two to three days. The depletion may be increased rather than improved and surgical risk will not be lessened by further delay. In an occasional extreme instance of this kind, when ideal preparation cannot be attained by parenteral feedings, it may become advisable to proceed with gastric resection and at the time of surgery to perform concomitant jejunos-

tomies after the manner of Allen and Donaldson. These surgeons recommend that two catheters be placed into the jejunum below the gastrojejunostomy, with the one catheter extending beyond the anastomosis into the gastric stump for decompression and the second catheter extending downward into the jejunum for postoperative feeding. This will afford the malnourished patient protection against postoperative edematous obstruction and at the same time allow early enteral feeding. This will be seldom necessary, but the point should be emphasized that parenteral feeding does not substitute for enteral feeding over a long period. Furthermore, the prolonged use of nasogastric tubes is to be avoided.

GASTROSTOMY

For decades gastrostomy has been employed for the purpose of feeding the patient with esophageal obstruction, either from cancer or from stricture. Gastrostomies for this purpose may be a double purse-string inversion of a mushroom or plain catheter after the manner of Stamm, or a tubal valvular gastrostomy after the manner of Spivack, or other variations therefrom. At present a more common use for gastrostomy is as an adjunct to extensive abdominal surgery when gastric or intestinal distention can be anticipated, such as after radical resection of obstructing carcinomas of the colon and total colectomies for ulcerative colitis. Some surgeons use gastrostomy after limited gastric resection combined with vagotomy.

Farris and Smith use a special Foley catheter inserted into the anterior wall of the stomach and brought out through a stab incision at a point where the stomach is in normal apposition with the abdominal wall, insuring fixation of the visceral and parietal peritoneum with several sutures. This is done at the time of major surgery and suction is maintained in the postoperative period until the hazard of ileus is terminated. The patient is more comfortable than with nasogastric suction, particularly when the need for suction is prolonged. Placing this large and rather stiff rubber tube upward (cephalad) in the stomach serves to decompress the distended stomach and its excess contents yet does not withdraw the small volume of gastric content from the distal end of the stomach. This residue in the distal stomach may pass through the pylorus as normal peristalsis recovers.

ULCER WITH FREE PERFORATION

Peptic erosion may penetrate through the duodenal or gastric wall to produce a free perforation with escape of duodenal or gastric content into the peritoneum. By contrast, the posterior duodenal ulcer and occasionally the posterior gastric ulcer perforate into the pancreas without creating the emergency of peritoneal spill. When the acid chyme strikes the peritoneal surface a dramatic clinical picture results. The generalized upper abdominal pain is so severe that the patient becomes afraid to move, for the slightest motion increases the pain. He may vomit at the onset, the abdominal muscles become boardlike and leukocytosis and a slight elevation of temperature invariably follow. While in the first six to twelve hours the picture may be mistaken preoperatively for acute cholecystitis, acute pancreatitis or closed loop intestinal obstruction, after six hours or more the picture may be more often mistaken for acute appendicitis. The agonizing upper abdominal pain and rigidity by then may have become replaced by localized pain and tenderness over the right lower quadrant and the leukocytosis will have increased. This is due to gravitation of the free duodenal content down the right iliac gutter with beginning peritonitis in this dependent area.

When perforation occurs on an empty stomach, the peritoneal spill is less than when it occurs after a meal, a factor influencing the need for lavaging the peritoneum at the time of operation. Usually, a careful history, absence of liver dullness on percussion, and x-rays of the upper abdomen in the upright and left lateral decubitus positions demonstrating free air under the diaphragm will confirm the diagnosis. Air under the left diaphragm suggests perforation of a gastric ulcer. Severe pain presenting in the shoulders or root of the neck suggests perforation of the esophagus and this possibility should be ruled out before the abdomen is incised. A broadened mediastinum, a pneumothorax or hydropneumothorax, as demonstrated by chest x-ray, may be associated with rupture of the esophagus. The serum amylase level should be determined to rule out pancreatitis although a moderate elevation can occur from peritoneal absorption of this enzyme following spillage from the perforated duodenum, particularly if perforation follows a heavy meal.

Treatment. As in the case of any perforated abdominal viscus, the earlier surgical

intervention is accomplished the better. Except for uncontrolled hemorrhage, there is no abdominal surgical emergency in which each of the early hours of delay is more costly. Unlike perforations farther along the intestine, the acid chyme is not primarily infective, although secondary bacterial invasion becomes superimposed upon the chemical or enzymatic peritonitis. The insult to the peritoneum is roughly proportionate to the amount of the spill (greater if the perforation occurs after a meal) and the time interval between the perforation and its surgical correction. Within the first six hours, in an otherwise normal risk patient, the mortality is negligible. After this interval the mortality becomes appreciable as the peritoneum becomes more extensively involved and the patient becomes more depleted. Within the early period little preparation is necessary. In an exceptional case, shock persisting beyond relief of pain may suggest coincident bleeding. Thus only intensifies the emergency and adds the requirement for blood transfusion. It is wise to place a nasogastric tube before surgery if there is abdominal distention. By a consideration of the preoperative history combined with the operative findings, the surgical problem will be resolved into a preference between (1) simple closure of the perforation and (2) a more definitive primary attack for the ulcer diathesis, usually subtotal gastric resection including the perforated ulcer. In either case the peritoneum of the upper and lower abdominal fossae and pelvis should be carefully lavaged with normal saline to remove the acid, enzyme and food particles. Also, irrespective of the surgical procedure selected, preoperative and postoperative therapy must include repair of the metabolic derangement caused by the peritonitis which results from the escape of gastric and duodenal contents. Cope has emphasized the importance of plasma therapy and the adequate replacement of potassium and nitrogen losses. The adequacy of the fluid therapy program is best judged by the renal output.

Simple closure is applied in perforated duodenal ulcer when (1) there is historically an absence of chronicity and at laparotomy the edges of the perforation are soft rather than firm or cartilaginous, (2) the duodenum is not deformed to suggest recurrent episodes of ulceration or (3) the duodenal perforation is judged to be an acute erosion rather than the result of a chronic ulcer diathesis. Simple closure is also resorted to

for either the duodenal or gastric perforations seen late after diffuse peritonitis and a deteriorated state of the patient make gastric resection too hazardous. A technical consideration of importance is not to attempt a purse-string closure of the perforation. In the first place, this suture is difficult to place in the inflamed, edematous and friable duodenal wall and, of greater importance, invagination may result in obstruction of the duodenum during the postoperative period. An easier and more secure method is that of Roscoe Graham of tacking an omental graft over the perforation. The duodenocolic appendage of omentum adjacent to the inferior curve of the duodenum (between the duodenum and hepatic flexure of the colon) is useful in this procedure (Fig. 49). This is brought over the perforation and tacked with a few fine silk sutures to the duodenal wall. This seems preferable to a free omental graft and the sutures do not have to be taken close to the ulcer where the wall is friable. This appendage has proved so expeditiously useful in closing perforations and protecting duodenal stump closures after resection that I have termed it the "providential omentum." The peritoneum should be thoroughly lavaged and the abdomen closed without drains. A gastrostomy or a nasogastric tube may be used to protect the closure and as a therapeutic measure if peritonitis and ileus are present.

Primary gastric resection including the perforation is preferred to simple closure (1) if an ulcer diathesis of long standing has been well documented, (2) if by previous hemorrhage, obstruction, or intractability to a proper regimen the ulcer would qualify for resection and (3) if the perforation at laparotomy is bordered by firm scar or deformed duodenum and provided advanced generalized peritonitis does not rule against this more involved surgery. Coincident hemorrhage and obstruction are also indications for primary resection.

If the perforated gastric ulcer is not resected, at least biopsy should be performed. Because gastric ulcers are more difficult to close and because malignancy is always a possibility in gastric ulcer, preference is for primary resection for the perforation proximal to the pylorus. Simple closure has been more commonly employed in the past in this country. In most reported series it has been found that about 50 per cent of patients with simple closure will have no more trouble, whereas the other 50 per cent will require further treatment and often secondary

Figure 49 For closing over the perforated duodenal ulcer the tag of gastrocolic omentum adjacent to the duodenum is tacked in a circumferential manner over the perforation with interrupted, fine, nonabsorbable sutures

surgery. When there is reasonable doubt as to the necessity for resection, it would seem wise to apply simple closure even though a few patients may require a second operation. It is often difficult to evaluate satisfactorily the clinical picture in the emergency and thus is particularly true in the average patients seen in the charity hospital, where a high percentage of ulcer operations are either for perforation or massive hemorrhage.

The third alternative, nasogastric suction and supportive treatment as a substitute for surgery, has been explored by Seeley and Campbell. It has been adopted by others for the patient seen late after perforation and when the clinical picture is then one of advanced peritonitis rather than perforation. However, I do not subscribe to the method even in these cases. The best treatment for advanced peritonitis associated with ileus, a spiking temperature and leukocytosis is emergency preparation of the patient by gastric suction and antibiotic, electrolyte and fluid support, followed promptly by laparotomy. Laparotomy is now primarily for evacuating fossae and loculated interintestinal pockets of pus. This is accomplished by stripping the intestine and irrigating the peritoneum with copious amounts of saline to which has been added penicillin and streptomycin. The perforation which by now has been sealed over with exudate is nevertheless securely closed over by omentum and gastrostomy is performed to relieve the distention of the peritonitis. The mortality in these desperately late cases is extremely

high, but some patients may be saved by these heroic methods—more, it is believed, than by gastric suction alone. This method of treating peritonitis has been described by Burnett and others following perforative appendicitis, is supported by my experience in a limited number of similar cases and should apply, I believe, for peritonitis following perforated ulcer. It is admittedly unorthodox and will require more than present accumulated experience to prove the superiority that I prophesy for it.

GASTRODUODENAL HEMORRHAGE

General Considerations. Approximately 20 per cent of peptic erosions bleed and 5 per cent bleed massively. Melena is evidence of active penetration of the ulcer. It is not in itself an indication for surgery. When associated with evidence of shock, such as clammy perspiration or faintness, a dangerous amount of blood (1500 cc. or more) may have been suddenly lost. Uncontrolled hemorrhage or recurrent episodes of severe bleeding are indications for surgery. Often the patient is brought to the emergency room with the story that he has fainted in the bathroom after "vomiting a bowlful of blood." The physician then faces the problem of determining the site of bleeding and the volume and rate of blood loss. He must promptly pursue a dependable course which will control the emergency. This can be a challenging responsibility. The inherent difficulty is in determining which patients will cease bleeding by conservative measures and which will die from lack of surgical control

of the hemorrhage. This must be accomplished before the emergency state of shock becomes irreversible. Sources of potentially fatal bleeding are for the most part in the upper gastrointestinal tract, i.e., above the ligament of Treitz. For practical purposes they may be divided into three groups: (1) esophageal and gastric varices resulting from portal hypertension; (2) acute transient erosions and hemorrhagic gastritis, for which gastric resection represents an unjustified sacrifice except as an emergency control of the hemorrhage to save life, and (3) the chronic peptic ulcer.

Carcinoma rarely causes massive hemorrhage although it may cause melena. Ulcerating lymphosarcoma of the stomach, however, not infrequently bleeds massively. It is estimated that 90 per cent of all upper gastrointestinal bleeding is from peptic ulcer. This is in keeping with the prevailing high incidence of peptic ulcer. The surgeon who has seen penetration and erosion into an artery in the crater of an ulcer can appreciate that such bleeding can be fatal. Blackford, Smith and Affleck showed that in a six-year period in Seattle, with a population at the time of 350,000, there were 151 deaths from hemorrhaging ulcer. Allen simultaneously pointed out that hemorrhage in the older patient was often fatal.

In general, hemorrhage has been defined as massive when the hematocrit value drops as low as 30 per cent and the erythrocyte count to three million or less. It is obviously massive if shock is associated. With the patient horizontal in bed, incipient shock and the degree of blood loss may not be appreciated but may be demonstrated by elevating the head of the patient—an observation referred to as the "tilt test" by Green and Metheny. An application of this test is seen when the patient with considerable acute blood loss into the intestinal tract may not appear shocked until taken to the x-ray room and placed upright for fluoroscopy.

Treatment. A few working principles are applicable at the bedside. Hemorrhage must be stopped before hemoglobic hypoxia results in irreversible damage to such vital organs as the brain, kidneys, liver and heart. If bleeding cannot be controlled by medical measures, of which early and continuous blood transfusion is the most important, then control by surgical operation must be considered. During this trial period, the gastric acid must be continuously aspirated or buffered by frequent feedings. Gastric aspiration by tube not only serves to with-

draw the acid but may prove a guide to continued bleeding as well. Local application of thrombin preparations has not proved helpful. The older the patient, the more arteriosclerotic and the more susceptible to hemoglobic hypoxia his vital organs may be and, therefore, the shorter the interval period before an irreversible state is reached.

Costello has shown that early and adequate blood replacement appreciably reduced the high mortality of an earlier period when transfusions were used less often. He also found that in some who were operated upon late for rapid deterioration, the bleeding vessel had in reality thrombosed and the critical picture was the result of irreversible shock rather than continued bleeding. The importance of immediate massive blood replacement for massive loss is apparent. It protects the patient from hemoglobic hypoxia and the measure of such replacement, as correlated with repeated blood counts, is the most dependable indication of continuing hemorrhage. If surgery then should become necessary for control, the mortality will be less if hemoglobic hypoxia has been prevented during the evaluation period. The patient whose blood counts continue to fall in spite of generous blood replacement during the early hours of observation, particularly the patient in the older arteriosclerotic age group, must be seriously considered for emergency surgery.

Unfortunately, there is no laboratory test which can be used as a guide to the cessation of hemorrhage. The best rule to follow is constant observation of the patient. If the pulse remains fast, the blood pressure lowered, the hematocrit value lowered, and if the patient is perspiring despite continuous blood replacement, then common sense indicates that bleeding continues. The internist should evaluate the general risk of the patient and the surgeon should be in constant consultation until the emergency is controlled, either by medical measures or by surgical intervention. Patients over age fifty, and particularly those with obvious arteriosclerosis, should be candidates for early emergency surgery. Age is not the sole factor in this decision. Other indications besides age and arteriosclerosis which lead one to individualize in favor of surgical intervention are: (1) history of previous hemorrhage or perforation; (2) the repeated vomiting of large quantities of blood, attesting the erosion of a large artery; (3) the patient with a long ulcer history to suggest extensive scarring which

might interfere with clot retraction, (4) the patient with proved gastric ulcer, (5) the patient whose hemorrhage is associated with pyloric obstruction and (6) the patient who starts to bleed again within the hospital on a good regimen. Under these conditions, massive hemorrhage is less likely to stop.

Recurrence of bleeding after a temporary cessation is a bad omen and probably results from acid or mechanical dislodgment of a pin-point clot. It should be remembered that it is difficult to revive a shocked patient twice. The consulting team by sustained observation should decide within the first twenty-four hours, or at the most forty-eight hours, which policy is to be followed. Surgery after this golden period carries a proved higher mortality than an adequate medical regimen. It has been shown that often when an operation is performed late, the vessel has thrombosed and the symptoms of persisting shock, which prompted late surgery, were actually symptoms of cerebral hemoglobin hypoxia and late surgery only hastened death. If driven by the deteriorating state of the patient to consider surgery late in the course of massive bleeding, certainly one should first prove by continuous gastric suction that the patient is still bleeding.

Of practical importance in timing surgery is the local availability of the patient's type of blood. Should he prove to be one of the rarer Rh negative types the clinician will be less prone to temporize. To give other than the ideal type blood without removing the source of bleeding would be hazardous for the patient's future. The question of recently administered adrenocortical hormone should be explored both from the standpoint of its being a factor in the hemorrhage and for necessary substitution hormone therapy should surgery be performed.

In those patients in whom emergency surgical intervention is decided upon to control bleeding, the surgeon is in most instances committed to subtotal gastric resection as the only means of accomplishing control, even if the point of hemorrhage cannot be demonstrated. Because of this, the surgeon should be certain of several points before sacrificing two-thirds or more of the stomach. These points should have been clearly established before operation. (1) that hemorrhage does arise from the upper gastrointestinal tract, (2) that it is not from esophageal varices, (3) that it is not the result of a blood dyscrasia and (4) that there is x-ray evidence of an ulcer.

The first of these, that the bleeding is above the ligament of Treitz, can be determined, if not already proved by frank hematemesis, by Levin tube intubation and aspiration of blood. Gastric ulcer and esophageal varices are usually associated with frank hematemesis, whereas duodenal ulcer may be manifested only by melena. The second point, that the bleeding is not from esophageal varices can be determined by emergency fluoroscopy, reinforced by a careful history and tests of liver function. Bleeding from this source is no less an emergency, but the surgical approach is different. Emergency fluoroscopy, in addition to assisting in ruling out varices, will often show the deformity of an ulcer, if not the ulcer crater, and in the opinion of most authorities the test is not a greater hazard than a blind search by the surgeon at the time of laparotomy. It is no more tragic for the patient to die in the x-ray room than for him to die in his hospital bed or the operating room. Adequate blood replacement is his best protection and blood can be administered in each of these places while the diagnosis is being established.

The more fortunate patients in whom an ulcer has been previously documented by x-ray examination need not be subjected to the additional hazard of further x-ray examination. Blood dyscrasia can on occasion be detected by platelet count and bleeding, clotting and prothrombin time. Instances of severe gastrointestinal bleeding associated with thrombocytopenic purpura have been observed. These basic tests should be made at the initial hospital admission when the blood is drawn for the first crossmatching.

Anesthesia. When operation is decided upon, the anesthesiologist should join the team of consultants and help with the choice of the anesthetic agent. The patient with an ulcer which is bleeding slowly or intermittently, and whose blood volume and blood pressure can be maintained easily by blood transfusions, may be operated upon with use of either a regional block technique or general anesthesia. On the other hand, the anesthetic most often employed for the patient whose ulcer is bleeding profusely, and whose blood volume and pressure cannot be maintained easily, is general anesthesia with or without a muscle-relaxant drug. Regional techniques, which dilate the vascular system in the area anesthetized and thereby cause a blood pressure fall, are usually contraindicated in the patient who has lost a great deal of blood.

Figure 50. The technique of Alfred Strauss for resecting the posteriorly perforating duodenal ulcer. The anterior wall of the duodenum is divided distal to the pylorus, the posterior ulcer is visualized, the posterior wall of the duodenum is then transected distal to the ulcer and the proximal edge of the transected duodenum is retracted upward as the surgeon dissects the ulcer from the pancreas in a proximal direction (Strauss, A. A., Strauss, S. F., Schwartz, A. H., and Kram, D. D., J.A.M.A., vol. 149).

Regardless of the type of bleeding or the type of anesthetic technique employed, precautions must be instituted to assure means of administering fluids, blood and drugs and to prevent aspiration of stomach contents into the tracheobronchial tree and facilitate oxygenation of the patient.

The patient should be intubated with a cuffed endotracheal tube while he is awake and under local anesthesia. The endotracheal tube assures a means of oxygenating the patient while the inflated cuff on the tube prevents aspiration of blood or blood clots should they be regurgitated from the stomach.

At the end of the operation, the patient should remain in the operating room until: (1) he is awake, (2) his respirations are judged to be adequate and (3) his mouth, pharynx and tracheobronchial tree have been cleansed by suction of mucus and/or regurgitated stomach contents.

At laparotomy the surgeon must remember that even when an ulcer of the stomach or duodenum is demonstrated, there may still be smaller erosions which may be the primary or an additional source of bleeding. To control the emergency, the ulcer should be resected. If it has penetrated through the duodenal wall into the pancreas, the duodenum must be separated from the pancreatic crater base.

A technical variation which may prove helpful in this trying situation is that of

Strauss (Fig. 50). In contradistinction to elective resection, a bleeding ulcer cannot be safely excluded into the duodenum. Transfixation of the end of an eroded artery, leaving the ulcer crater exposed to the digestive juices, may result in delayed recurrent hemorrhage. Likewise, the posterior surface of the duodenum should be carefully explored for secondary points of bleeding and the gastric stump that is preserved should have its mucosal folds carefully visualized all the way into the cardioesophageal juncture. This is best accomplished with an endoscope. Unfortunately, a large number of patients with massive hemorrhage are obese individuals in whom this ideal is difficult to accomplish. Before the abdomen is closed search should be made for a coincident Meckel's diverticulum, which might harbor heterotopic gastric mucosa and give rise to secondary bleeding. Evidence of cirrhosis of the liver, enlargement of the spleen or an engorged portal venous system suggesting portal hypertension should be searched for and these findings, or their absence, should be carefully recorded as a helpful reference should there be recurrent hemorrhage.

RECURRENT GASTROJEJUNAL ULCER

The development of gastroduodenal ulcer is evidence of failure in the individual case of the procedure applied. The incidence of recurrent ulcer has been reported as high as

34 per cent following gastroenterostomy and in the United States has averaged between 5 and 35 per cent. This led eventually to the abandonment of gastroenterostomy as a primary attack for ulcer. However, the fact that no procedure today gives completely dependable control in all patients is attested by a continuing incidence of recurrent ulcer in the neighborhood of from 2 to 4 per cent following 70 per cent distal gastrectomy, and approximately 5 to 10 per cent after vagotomy combined with gastroenterostomy. Recurrent ulceration, according to Thompson, is prone to manifest itself earlier after gastrectomy than after gastroenterostomy.

In the treatment of recurrent ulcer, medical measures should be of course tried first. Recurrence may be due to a period of unusual emotional stress. Medical treatment, favored by the altered physiology already accomplished by surgery, may suffice in some of these minor recrudescences. In general, however, recurrence indicates an unusually severe ulcer diathesis and reoperation may become necessary. In reviewing 617 operations performed on 586 patients at the Mayo Clinic for gastrojejunal ulcer, Walters, Chance and Berkson concluded that vagotomy can be expected to give excellent results in 70 per cent of those ulcers which follow adequate gastric resection. It carries a low operative risk and whether the trans-thoracic or transabdominal route is used makes little difference as far as the ultimate result is concerned, although they prefer the abdominal approach for more thorough exploration. When the recurrent ulcer follows simple gastroenterostomy they found gastric resection to be superior to vagotomy, yielding excellent results in 86.5 per cent of 111 traced cases as compared to 77.8 per cent for vagotomy alone. Whereas the mortality was only 1 per cent following simple vagotomy in the postresected cases, re-resection in these cases carried an operative mortality rate of 15 per cent. It is the belief of some surgeons, however, that re-resection should be done when the ulcer crater is found to be indurated. In such instances, healing would be slow and unsure despite the control of hypersecretion by vagotomy. When re-resection is necessary, vagotomy should still be added and, according to Walters, will not increase the mortality.

Before operation for recurrent ulcer, as in all severely intractable cases, the clinician and surgeon should consider the possibility of hyperfunctioning islet alpha cell tumor of the pancreas. Since Strom first described

this condition, Zollinger and Ellison have collected from their own and other experience forty-three cases in which islet cell tumors were related to peptic ulcer. Since these are non-insulin-producing islet cell tumors, it is believed that the hyperglycemic-glycogenolytic factor of the pancreas, glucagon, may be the factor stimulating the gastric secretion to abnormal levels. Earle, Cahill and Hoar have published contrary observations on man and animals showing that glucagon administered over short intervals reduced blood pepsinogen levels as well as the milliequivalents of gastric acid secretion. This effect was apparently not dependent on intact vagi since vagotomized animals showed a similar inhibition. While evidence points to a potent pancreatic ulcerogenic factor of some form, this work tends to disprove glucagon as of any importance in peptic ulcerogenesis. Preoperative laboratory tests are not of help and only careful surgical exploration will discover this rare cause of intractable ulcer.

Likewise, at operation, in addition to careful exploration of all surfaces of the pancreas for such a tumor, the surgeon should look for other causes of failure of the previous gastric resection, such as an overlooked portion of excluded gastric antrum (persisting hormone stimulation), an inadequate resection of the body of the stomach (too large a residual target), incomplete vagotomy in those cases in which the primary attack was based on removing the neurogenic phase of stimulation, and a long proximal jejunal loop (less concentrated alkaline protection of the anastomosis). If the primary attack was vagotomy, the Hollander insulin test or the balloon motility test may be used as a guide to the completeness of the previous vagotomy before operation is performed for recurrent ulcer.

GASTROJEJUNOCOLIC FISTULA

This condition is seen with less and less frequency since simple gastroenterostomy has been abandoned. It occurs as a result of a marginal ulcer, usually situated at the anastomosis or in the efferent loop just distal to the anastomosis, penetrating through the wall into the overlying colon. With penetration through this barrier, a fistula between the stomach or jejunum and colon is thereby established. This results in a fecal odor to the breath and rapid transit of food through the intestinal tract because of the irritation to the small bowel by the regurgitant feces. A marked loss of weight usually results. The

diagnosis is discovered more readily by colon x-ray than by x-ray of the stomach. In advanced cases, the diagnosis is evident from history alone.

Correction of this condition involves the take-down of the fistula plus gastric resection to control the severe ulcer diathesis. After diagnosis, some of these patients may, by blood transfusions and parenteral feedings, have some of the lost weight restored and be eligible with the aid of antibiotics for a one-stage resection of the fistula and subtotal gastrectomy.

Prior to present-day preoperative and postoperative adjuncts it was more often advisable to stage the procedure. This requires diverting the fecal stream proximal to the fistula, which is in the transverse colon, and thereby preventing the feces from entering the stomach and jejunum and from traversing the small bowel. It can be accomplished in several ways. Pfeiffer and Kent were the first who recorded staging by performing a colostomy on the ascending colon. Baker independently accomplished the same with an ileostomy of the terminal ileum and Lahey avoided the exteriorized diversion by an anastomosis of the terminal ileum end to side with the descending colon distal to the fistula. Since this is a permanent anastomosis, the entire colon proximal to the fistula is resected at the second-stage operation. In the procedures of Baker and Pfeiffer, no bowel is sacrificed and the ileostomy or colostomy is closed at the second-stage operation when the fistula is resected and a subtotal gastrectomy done.

CHRONIC GASTRIC ULCER

Pathogenesis and Surgical Treatment. As contrasted with those in the duodenum, ulcers less often become chronic in the stomach, although the equal distribution of erosions in the duodenum and stomach on routine autopsies suggests that erosions often form in the stomach and heal without becoming chronic. The incidence of chronic gastric ulcer is but one-ninth that of chronic ulcer of the duodenum. Also, it is of some differential significance that the chronic gastric ulcer, by contrast with the duodenal ulcer, is associated with little if any elevation in the normal acid secretion.

Dragstedt and his associates attribute gastric ulcer to an exaggeration of the hormonal gastric phase of secretion and the duodenal ulcer to an overactive and prolonged neurogenic phase. For this reason, they believe that vagotomy is not the preferred operation

for gastric ulcer and it should not be substituted for distal gastrectomy. It is established that distal gastric resection for gastric ulcer is seldom complicated by recurrent ulcer even though the resection is not more than 50 per cent. For gastric ulcer, therefore, many authorities substitute a partial 60 per cent distal resection for the usually higher resection (75 per cent) used in duodenal ulcer. Whereas in duodenal ulcer there is no concern for malignancy, this is a major consideration in gastric ulcer and one of the cardinal requirements in the surgical treatment, therefore, is the removal of the ulcer for histologic study.

To protect against recurrent peptic ulcer, the other requirement is removal of the entire antrum and a portion of the target body. Since more of the stomach is preserved in resection for gastric peptic ulcer and since the uninvolved duodenum lends itself well to anastomosis, gastroduodenostomy (Billroth I) is the customary method of restoring continuity. The mortality following gastric resection for gastric ulcer is lower (less than 1 per cent) than for duodenal ulcer, since the resection carries through normal unscarred duodenum which can be more safely closed or anastomosed. Resection gives more dependable control of the ulcer diathesis than is true when applied for duodenal ulcer and, possibly, since a lesser resection suffices and an *is* more eas *is* lae may at k

One word of caution should be sounded in reducing too generously the resection for gastric ulcer. The gastric ulcer may be associated with or be secondary to duodenal ulcer. In such an instance the more extensive resection done for duodenal ulcer should apply. Johnson finds gastric ulcers or their scars associated in some 10 per cent of patients subjected to gastrectomy for duodenal ulcer. These patients have the hypersecreting duodenal type rather than the hyposecreting hypomotile gastric ulcer. In two-thirds of these, there was pyloric stenosis and gastric retention and he suggested that this retention of acid is an etiologic factor in the development of such associated gastric ulcer. Because of the fact that the two may be associated, plus the fact that recurrence after gastric resection for gastric ulcer is occasionally seen, the surgeon should exercise caution in reducing the amount of resected stomach below 60 per cent. If a long-standing history of ulcer and previous roentgenologic evidence of duodenal deformity sug-

gest previous coincidental duodenal ulcer, then the resection should be less conservative, particularly if preoperative testing shows the gastric secretion is excessive.

In general, the technical problems are not as great in resection for gastric ulcer and the mortality is less than after resection for duodenal ulcer. The exception to this is the penetrating ulcer high on the lesser curvature close to the esophageal juncture. This situation has prompted some surgeons to resort in these instances to gastroenterostomy and vagotomy, an attack which may be, as Dragstedt believes, without physiologic support. Others, for the same technical reasons, have done a distal gastric resection leaving the high ulcer. Both of these methods fail to rule out malignancy. Certainly total gastrectomy is not justified in such instances without histologic proof by frozen section of malignancy. I have not encountered an ulcer that, after adequate mobilization of the entire stomach, could not be resected in the Hofmeister manner, leaving some stomach. In these instances, the Hofmeister clamp, if placed above the high ulcer, might encroach upon the esophageal juncture and for this reason the use of the clamp is omitted (Fig 51 a and b). Instead, the stomach is freed entirely on the greater and lesser curvatures, the field is isolated by packs, a clamp is put part way across the greater curvature side marking the level of anastomosis, the greater curve side of the stomach is transected distal to the clamp and then a freehand vertical resection of the lesser curvature, including the ulcer, is accomplished. The open margins of the lesser curvature are then closed under direct vision in layers so as not to encroach upon the opening of the esophagus. The greater curvature side, which has been held by the clamp, is then anastomosed in the usual manner.

Indications for Operation for Gastric Ulcer. Whereas for duodenal peptic ulcer surgery is advised only for the 15 per cent who suffer from the complications of chronic recurrence, by contrast in gastric ulcer the incidence of cancer which is mistaken for peptic ulcer leads the clinician to advise surgery in from 30 to 75 per cent. It is generally agreed that the gastric ulcer deserves surgical consideration as long as it remains unhealed. The all-important question is whether or not all gastric ulcers should be promptly subjected to surgery. Reference here, of course, is to those ulcers which cannot be diagnosed by x-ray or other measures as being frankly malignant.

In favor of such a policy would be the argument that the issue would thus be rapidly and, from the standpoint of cancer, more safely settled. Against this argument is the fact that gastric resection is not without mortality and morbidity and, furthermore, medical treatment does prove effective in healing probably 50 per cent of these ulcers. Precipitate surgery would result in some instances in gastric resection for acute erosions which are not actually chronic ulcer and which do not justify sacrifice of the stomach. Certainly, as in duodenal ulcer, a medical trial is worth while in a considerable number of previously untreated gastric peptic ulcers. Marshall found that in 411 gastric ulcers without gross evidence of cancer, 37 per cent came to surgery and 15 per cent proved to be malignant. It is remarkable that 50 per cent of the patients who proved to have malignant ulcer gave a history of ulcer distress for five or more years. From this study, Marshall concluded that probably 50 per cent of gastric ulcer patients deserved immediate surgery. In 161 cases of gastric ulcer without gross evidence of cancer which Jones, Clements and Pearson reviewed, 55 per cent were operated upon and of those, 9 per cent proved to be malignant. Of the seventy-three patients (45 per cent) who were treated medically, twenty-five had recurrence of their ulcer and five subsequently came to surgery. One of these proved to be malignant. Forty healed and remained well but required follow-up x-ray examination for insurance against recurrence.

Preoperative differential diagnostic methods for malignancy should include, of course, a careful history and physical examination to discover distant metastasis such as Virchow's lymphatic metastasis in the neck, a nodular liver or a cul-de-sac implant presenting as a rectal "shelf." The absence of free gastric acid secretion on repeated analysis is strongly in favor of malignancy although the presence of free acid does not rule out malignancy. The roentgenologist can catalogue the definitely malignant and a large portion of the definitely benign, but in the borderline group between these two extremes, he will not give assurance.

In most centers histologic evidence of cancer is found in 10 per cent or more of ulcers which have preoperatively been considered benign. Radiologic signs favoring malignancy are the meniscus resulting from the rolled border, an ulcer greater in diameter than 2 cm, particularly when it is with-

t proportionate penetration, and the ulcer's situation on the greater curvature or pyloric region rather than on the magen-asse. Cytologic studies on the gastric as-ate may, if the findings are positive,

prevent delay in surgery. As far as the threat of malignancy in the gastric ulcer is concerned in borderline cases, the majority of internists and surgeons insist on from ten to fourteen days of rigid medical control,

Figure 51. A method of resecting the ulcer high on the lesser curvature of the stomach. After the stomach is freed and the duodenum transected, the level of resection and anastomosis is marked on the greater curvature by a Payr clamp. Then, without the aid of vertical clamps which might encroach upon the esophagus, the ulcer and lesser curvature are removed by sharp dissection. (a) anterior view (left) and (b) posterior view (right). c, This vertical lesser curvature incision is then closed with two rows of sutures under direct vision and the greater curvature stump is anastomosed to either the duodenum or jejunum.

with bed rest, hourly feedings and antacids. If 50 per cent healing cannot be demonstrated, the patient should have surgery. The majority of these ulcers will not prove to be malignant, but nonetheless they represent a complicated peptic ulcer which should have the benefit of surgery before such complications as penetration and hemorrhage increase the hazard.

Patients with gastric ulcer are, in general, poorer surgical risks than patients with duodenal ulcer. They average ten years older than patients with duodenal ulcer and will have a proportionate increase in associated arteriosclerosis and other constitutional diseases. Those ulcers which do show satisfactory partial healing in two weeks should be proved to have completely healed in six weeks and should be x-rayed several times in the first year thereafter to prove that they remain healed. If the ulcer should recur, surgery is preferable to further confusing delay.

Even at operation differentiation between cancer and chronic peptic ulcer may still be difficult in these borderline cases. The ulcer in the distal stomach presents a lesser problem in this regard than does the ulcer situated high in the stomach because the resections for benign and malignant ulcer in the prepyloric area are essentially the same, except that in cancer the greater omentum is included in the resection and an attempt is made to remove more duodenum and to include the subpyloric and regional lymphatics.

On the other hand, for the higher ulcer near the esophageal juncture, resection is done without clamps (Fig 51c). If frozen section proves the ulcer to be cancer, a total resection of the remaining stomach is justified to insure a greater margin against local recurrence, unless lymphatic metastasis is also discovered. In the latter case, the chance for control may not be adjudged sufficient to justify the additional mortality and morbidity of total gastrectomy.

The radical cancer operation is not justified in borderline cases without first having histologic proof of cancer. It should also be remembered that large gastric ulcers penetrating the pancreas or lesser curvature are more often benign. They should be stripped off the pancreas without injury to that organ.

ESOPHAGITIS AND ESOPHAGEAL PEPTIC ULCER

Peptic ulcer of the esophagus occurs with extreme rarity, as compared with either gas-

tric or duodenal ulcer, for the simple reason that the esophagus is not exposed to the gastric acid secretions except under unusual situations. One of these occurs by regurgitation when the esophageal sphincter mechanism is deficient, particularly as in sliding hiatal hernia. The second, and much rarer, situation is when heterotopic gastric secreting mucosa occurs above the cardiac sphincter.

The esophagus is more vulnerable to peptic erosion than is the rest of the gastrointestinal tract. It is protected physiologically against acid reflux by a sleeve of alkaline secreting cardiac glands and mechanically by the angulation of the entrance of the esophagus and by the sphincter action of the cardioesophageal junction. Transient esophagitis or erosions may follow reflux from repeated episodes of vomiting or occur when the sphincter is made incompetent by esophageal varices and by the prolonged use of indwelling nasogastric tubes. Esophagitis from prolonged exposure to acid-peptic secretion may become symptomatic with or without erosion. The erosions from reflux are more often linear and stenosis may eventually result. The circular punched-out crater similar to that seen in chronic peptic erosion of the duodenum is found more often when the terminal esophagus is lined by columnar epithelium similar to that in the stomach. As in the duodenum such an ulcer may bleed or it may, by repeated recurrence and healing, lead to stenosis and obstruction. At this stage it may be difficult to determine whether the stenosis is the result of regurgitant esophagitis alone or recurring peptic ulceration. It might even be confused by the clinician with the obstructive achalasia referred to as cardiospasm, although the roentgenologic characteristics of this entity, including the greater esophageal dilatation, serve to differentiate it.

Surgical treatment may require (1) simple repair of a sliding hiatal hernia to eliminate reflux, (2) an operation to control hyperacid secretion, (3) bougienage for, or the resection of, a stenotic terminal esophagus, (4) the interposition of a loop of jejunum or colon to replace an incompetent sphincter, or (5) a combination of one or more of these procedures.

For symptomatic esophagitis associated with sliding hiatal hernia but without stenosis or associated duodenal or gastric ulcer, the correction of the reflux may be all that is required. Medical treatment, including weight reduction, antacids and elevation of

the head of the bed, should relieve the majority. In about 30 per cent, surgical correction of the hiatal hernia will be justified. If the disorder is intractable to adequate medical treatment, surgery should not be indefinitely postponed because the complications of stenosis and hemorrhage in the elderly patient are graver problems. When esophagitis is associated with a hiatal hernia and in addition there is a duodenal or gastric ulcer, repair of the hernia should be combined with one of the operations previously described to drain the stomach and control the hypersecretion of acid.

Even after obstruction of the terminal esophagus has complicated the picture, Wangenstein and Levin found that gastric resection relieved several patients previously treated by dilatations. Barrett has described a chronic peptic ulcer in the terminal esophagus which is encompassed by columnar rather than the usual squamous epithelium. Whether the ulcer was incited at the beginning by congenital ectopia of gastric mucosa in the terminal esophagus above the cardiac sphincter mechanism or whether the columnar epithelium is heterotopic, resulting from repeated healing of ulceration secondary to acid regurgitation, is by then of no importance. Surgical attack for such a cardioesophageal ulcer requires resection of the involved terminal esophagus, plus an attack designed to reduce acid secretion. An additional procedure is necessary to protect the terminal esophagus, which will thereafter, by virtue of the loss of the cardiac sphincter, be more exposed than before.

Ellis has advocated a sleeve resection of the involved terminal esophagus with reanastomosis of the terminal esophagus to the cardia of the stomach. This is then supplemented by distal resection of the antrum of the stomach, vagotomy and Billroth I gastroduodenostomy. Since 1955, Ellis has applied this procedure in twenty-seven patients. There was one operative death and one patient has required repeated dilatations. The others have had satisfactory results, fifteen excellent, eight good (occasional nausea and vomiting) and three are too recent to evaluate. Twenty-four of these patients had developed their esophageal lesion secondary to sliding hiatal hernia. Three had undergone previous cardioplasties of various types for cardiospasm.

When the esophageal stricture is not associated with duodenal ulcer or deformity, after resecting the stenotic or incompetent cardioesophageal juncture, Merendino preserves the stomach and protects the esoph-

agus by the interposition of a jejunal segment between the esophagus and the stomach, combined with bilateral vagotomy and Finney pyloroplasty. He and others have shown that once the sphincter mechanism is lost, and the esophagus is then anastomosed to the stomach, the esophagus becomes vulnerable to acid regurgitation, and ulcer and hemorrhage are frequent sequelae. They find the interposed jejunal loop adequately substitutes for this sphincter mechanism and they prefer this to attempts to reduce acid secretion. In the thirty-three operations performed, there have been four operative deaths, a mortality of 12.1 per cent. The patients varied in age from ten to seventy-five years and the series included not only patients with peptic esophagitis and stricture, but also patients with cardiospasm and esophageal varices (extrahepatic type) and lye stricture. Of the twenty patients with peptic esophagitis and stricture, all are satisfied with the result. They report no failure to cure the esophagitis, no recurrent ulceration and no new ulceration of the upper gastrointestinal tract. The operation is prolonged, difficult and the hazard of an insufficient blood supply to the transposed jejunum can be a major consideration.

UNTOWARD RESULTS OF SURGERY

Mortality. Except in the case of uncontrolled hemorrhage, unrelieved obstruction or perforation, peptic ulcer in itself is not a fatal disease. Therefore, any surgical procedure applied should be critically appraised on the basis of mortality.

Operative mortality stems, for the most part, either from technical imperfections which result in leaking gastrointestinal anastomoses or leaking duodenal stumps, from peritonitis and from pulmonary complications or from cardiovascular accidents. In some patients with massive hemorrhage, exsanguination and hypoxia may be responsible for death. Pulmonary complications, a frequent cause of death twenty-five years ago, have been appreciably reduced by use of antibiotics, preoperative suction of the stomach to prevent pulmonary aspiration and postoperative tracheal suction. Cardiovascular accidents have been reduced by improved anesthesia, anticoagulants, blood replacement and pharmacologic support of blood pressure. These will continue to be responsible for an irreducible minimum of mortality, whereas technical imperfections, by good judgment and selection of surgical methods, may be individually improved.

The mortality rate reported by specialists

in this field varies from less than 1 to as high as 3 per cent following gastric resection for ulcer and from 0.5 per cent to 1.5 per cent after vagotomy. The mortality is understandably higher in charity hospital wards where surgery is more often done for uncontrolled hemorrhage or perforation than for intractability. Furthermore, patients in charity wards are usually poorer surgical risks than are private patients.

Possibly the more representative figures on mortality are those collected by the Ohio Chapter of the American College of Surgeons from twenty-nine hospitals in the state of Ohio and cited by Crile. The state-wide mortality for elective gastric resection was 4.9 per cent, whereas the mortality for operations exclusive of resection (mostly vagotomy with a gastric drainage procedure) was 1.7 per cent. These figures did not include deaths from emergency operations for bleeding or perforation. On the basis of these figures, Crile suggests that the over-all mortality would be much less if vagotomy and gastroenterostomy (or pyloroplasty) were done primarily and gastric resection reserved for cases of recurrent ulcer. The surgeon whose mortality is high with gastric resection should consider this advice. Certainly resection of the larger posterior penetrating ulcer should be individualized. In these cases, an appreciable reduction in the mortality of gastric resection can be accomplished by excluding the difficult ulcer into the closed duodenal stump (Fig. 48A).

In a comparison by Baker of subtotal gastrectomy with resection of the ulcer and of selective exclusion of the difficult posterior penetrating ulcer into the duodenal stump, mortality was found to be reduced from 1.9 per cent to 0.8 per cent by employing the exclusion method in the more difficult cases. It is noteworthy that of the three deaths in the 156 resected ulcers, two were from leaking stumps which should not have occurred with gastroenterostomy. On the other hand, there were no deaths due to technique in the 122 cases of difficult ulcer treated by exclusion, the single death being that of an eighty-year old man operated upon on the fifth day of a massive hemorrhage and dying of cerebral hypoxia. By application of this selective principle of exclusion, the last 140 gastric resections performed since completion of the previous study have been accomplished with only one death, an elderly patient operated upon in an emergency for exsanguination. It should be noted that the exclusion method was not followed by a

higher incidence of recurrent ulcer, there being one proved and three suspected recurrences in each series. In the difficult situation the surgeon should apply a method which has proved safest in his hands, even though it is associated with a higher rate of recurrent ulcer and even though in these few cases secondary operations be required.

The reported mortality of resection for gastric ulcer is approximately one-half that for duodenal ulcer, mainly because the normal duodenum presents no technical problems either in closure or anastomosis.

Incidence of Recurrent Ulcer. The next most serious complication to fatality is failure of the surgical procedure to control permanently the ulcer diathesis. Gastroenterostomy alone has been followed by gastrojejunal ulcer in up to 38 per cent; gastroenterostomy protected by vagotomy has been followed by gastrojejunal ulcer in from 5 to 10 per cent. Gastric resection has been followed by recurrent ulcer in from 2 to 4 per cent, the higher recurrence rate following the more conservative resection. A true 75 per cent gastric resection has a minimal recurrence rate, being less than 1 per cent in most reported series. The recurrence rate after antrectomy and vagotomy is less than 1 per cent. The recurrent ulcer is rare after 65 per cent gastric resection for gastric ulcer.

Dumping Syndrome. This term has been used to describe the tachycardia, palpitation, faintness, perspiration and sense of warmth or flushing some patients who have undergone gastric surgery experience shortly after meals. It more often follows ingestion of sweet liquids such as milk shakes and syrups, although it may follow any food. It probably should be differentiated from the "small stomach syndrome," in which the patient for the first few weeks after operation feels uncomfortably full after eating.

The incidence of "dumping" varies with different authors, ranging from 5 to 100 per cent. It probably is present, if searched for, in a minimum of from 15 to 20 per cent of patients for the first few weeks or months after gastric resection, and in from 1 to 5 per cent it may persist to a disabling degree. Its incidence will depend in part upon the individual's psyche (the migrainous patient, the fastidious eater, the introvert) and will depend more upon the extent of resection than upon the type of anastomosis employed. The extensive 75 to 80 per cent resection has been followed by a greater incidence of dumping than has the 60 per cent resection, however, individual susceptibility remains

an important factor and each patient should be carefully screened preoperatively with this in mind.

The actual cause of dumping remains obscure. Distention of the stomach or jejunum, the pull of the full stomach and jejunum on unsupported mesenteries, too rapid emptying of the stomach and reflux pooling of the blood in the splanchnic bed with resultant systemic hypovolemia have all been suggested as mechanisms. One of the more attractive recent theories is that of Roberts, Randall and Farr. They postulate that the osmotic pull of the jejunal contents after a carbohydrate meal produces fluid compartment and electrolyte shifts which deplete the circulating blood volume and thus creates this picture of mild shock. Certainly the clinical syndrome is one closely simulating syncope or shock.

Many methods of treatment have been recommended. Probably the most effective is to reassure the patient that the complication is neither serious nor permanent, to see that he carefully avoids taking liquids and/or sweet foods on an empty stomach and instead starts the meal with dry toast, poached eggs and other proteins. The majority of patients are relieved shortly after lying down. Reassurance seems the best treatment and time the best cure.

Nutrition. Failure of the patient to maintain his preoperative weight occurs in about one-fourth of patients after subtotal gastrectomy. A follow-up which was made of 278 patients showed 55 per cent to maintain their normal weight, 20 per cent to become overweight and 25 per cent to be under their preoperative weight. Why some patients should lose weight is not completely understood, but there are at least two responsible factors. First, the patient does not eat enough, either because of early satiety from the reduced gastric capacity or because of symptoms of dumping when larger meals are eaten. As a result, the caloric intake is frequently at such a level that weight cannot be gained or even maintained. This is probably the most common cause of weight loss in these patients. Second, assimilation studies have revealed that the absorption of both fats and proteins is reduced after gastric resection and even after simple vagotomy. This is probably of significance in only 10 to 15 per cent of these patients. The physiologic basis for malabsorption is probably inadequate stimulation of the biliary and pancreatic secretions as well as inadequate admixture of the food with these secretions

Both presumably result from the rapid transit of food through the stomach and intestine with limited contact of the food with the intestinal mucosa. The reduced transit time is explained in part by the reduced size of the stomach and the fact its outlet is no longer guarded by the pyloric sphincter. If the duodenum is by-passed, as in gastrojejunostomy, the loss of assimilation should be even greater than after gastroduodenostomy. In fact, studies confirm that the fecal fat and nitrogen loss is actually less after the Billroth I gastroduodenostomy than after the Billroth II gastrojejunostomy. Dietary supplements of pancreatic enzymes and bile salts are usually ineffective. The treatment, therefore, is purely dietary and consists of careful attention toward providing sufficient calories in the form of frequent meals of those foods which do not elicit dumping. Anticholinergic drugs may be of help in reducing the rapid transit of food through the intestine.

Tumors of the Stomach

By SAMUEL F. MARSHALL, M.D.

SAMUEL FREDERICK MARSHALL was educated at Johns Hopkins University and received his surgical training under one of the early Hopkins surgical residents who had become the Chief Surgeon of the Henry Ford Hospital. He joined the Lahey Clinic Staff in 1935 and his surgical skill and judgment have added to the reputation of that organization.

Tumors of the stomach consist of benign tumors and malignant tumors, but by far the larger number of gastric neoplasms comprise the carcinomas or gastric cancers. Malignant gastric tumors, moreover, may be carcinomatous or sarcomatous—the sarcomas accounting for approximately 3 per cent of all types of gastric neoplasms.

BENIGN TUMORS

The incidence and types of tumors, as ascertained by microscopic study of 1700 tumors consecutively removed by operation, are shown in Table 1. It will be noted that benign tumors account for 48 per cent of the total number of tumors found at the operating table, but the number of different benign tumors which occur in the stomach is small. It is probably true that they occur more frequently than noted at operation because they rarely give symptoms and thus are recognized less frequently than the malignant tumors which sooner or later always produce digestive distress.

One of the commonest benign gastric tumors is the simple adenoma of the stomach

which may occur as a single tumor or, more rarely, as a multiple polypoid form of tumor. Ewing pointed out that rarely these tumors are submucous in origin. The tumors ordinarily remain small and seldom give symptoms unless situated near the pyloric orifice where, when pedunculated, they may prolapse through the pylorus and cause obstructive symptoms. The common site of origin

Table 1. Classification and Incidence of 1700 Gastric Tumors

is in the antral area. They are frequently accompanied by achlorhydria and minor grades of anemia

Polyps may be multiple and produce diffuse gastric polyposis. They may be either neoplastic or inflammatory, but in most cases they are adenomatous. Multiple polyps, which occur as a result of inflammation and are related to advanced hypertrophic gastritis, produce diffuse gastric polyposis. Multiple discrete polyps may be scattered over the entire mucosal surface, but more often are localized in the lower third of the stomach (Fig. 52). We have seen instances in which they involved the entire stomach and on several occasions have found malignant degeneration occurring in multiple polyps, which are true adenomatous polyps in character. Other benign tumors encountered are the fibromas, fibroadenomas, lipomas, hemangiomas and occasionally a neurofibroma, but these are extremely uncommon. Feldman has stated that 25 per cent of gastric tumors are benign tumors and Stewart observed seventy-eight benign tumors of the stomach in 11,000 post-mortem subjects (0.7 per cent). There is considerable difference of opinion in the literature as to whether adenomatous polyps eventually become malignant. It appears, however, that while gastric polyps do not have the same tendency to degenerate into cancer as do polyps of the colon and rectum, malignant degeneration does undoubtedly take place and is a real danger.

Figure 52 Multiple polyposis of the stomach. One area showed adenocarcinoma.

There are no definite characteristic criteria by which malignant and benign polyps can be differentiated clinically or by roentgenologic examination. The only safe method, therefore, is surgical removal of all polypoid tumors of the stomach. A final decision regarding the malignancy or benignancy can be made only by pathologic study of the small tumor. Rigler and Erickson have stressed the precancerous nature of polyps and at the Lahey Clinic about 30 per cent of the gastric polyps removed at operation have proved to be malignant. Many of these tumors are pedunculated and can be excised locally and an immediate pathologic examination made of a frozen section. Should the tumor prove to be malignant, resection of the stomach should be carried out.

The commonest benign tumor is a *leiomyoma* which in some cases is very similar in structure to the leiomyoma of the uterus. This tumor almost always is single; it arises from the smooth muscle layer of the stomach and usually projects into the lumen of the stomach. Many of these tumors are small and rarely grow to a size that may prove to be of clinical significance. On the other hand, they may attain a very large size and in one of our patients the tumor was as large as a man's head. Boyd has stated that these tumors may undergo malignant change, forming leiomyosarcomas. Meissner is of the opinion that there is no proof that a malignant leiomyosarcoma arises from a pre-existing benign leiomyoma. He could find no evidence of such changes occurring in any of the specimens of smooth muscle tumors, benign or malignant, which he studied. We have had twenty-eight patients who have had operations for benign leiomyomas. There are no signs or symptoms which are pathognomonic of these tumors. The clinical course depends on the size of the tumor, whether the origin is near the gastric orifice where obstruction may be produced or whether ulceration occurs in the mucosa (Fig. 53) with resulting hemorrhage. It is impossible to determine clinically, on roentgenologic examination, or even by direct visualization of the tumor at operation whether these tumors are sarcomatous or benign. Because of this, they should be removed surgically. Resection is preferable to local excision unless the tumor is very small, uncomplicated and easily removed, provided also that an immediate microscopic examination verifies the absence of a malignant smooth muscle tumor.

The lipomas, fibromas, angiomas and neu-

Figure 53 a, Leiomyoma of stomach, partially resected stomach. Note ulceration of tumor. b, Discrete rounded intraluminal filling defect, leiomyoma of stomach.

rofibromas originate in any part of the gastric wall and are extremely rare; differentiation cannot be made on the basis of clinical or roentgenologic findings. The true pathologic state of these tumors cannot be recognized until they are excised and histopathologic examination is made.

One rare type of tumor arising in the stomach is *aberrant pancreatic tumor*. These tumors are of practical significance only because they produce filling defects as noted on the roentgenogram and may be confused with gastric polyps, peptic ulcer or even gastric carcinoma. Most of these tumors are located in the pylorus and the first part of the duodenum and are asymptomatic. They ordinarily arise on the greater curvature and are usually discovered incidentally upon roentgenologic examination of the gastrointestinal tract. Aberrant pancreatic tumors arising in the stomach have been noted in twelve patients. If gastrointestinal symptoms are present, they suggest peptic ulcer, pyloric obstruction, gallbladder disease or functional indigestion. Gastric surgery is indicated in these subjects to rule out the possibility of a malignant tumor or a prepyloric ulcer, which may carry the danger of malignant degeneration. In the majority of the patients, the tumor can be locally excised, provided a pathologic examination is carried out immediately and confirmation obtained of the benign nature of the tumor. Once these tumors are seen at the operating

table, the surgeon can, in the majority of cases, make a diagnosis from the gross appearance inasmuch as they are in the gastric wall and are submucosal in origin.

MALIGNANT TUMORS

Carcinoma is the most frequent form of malignant neoplasm arising in the stomach and comprises 90 to 95 per cent of all gastric tumors. Other tumors arising in the stomach include the sarcomas, or the malignant mesenchymal tumors, which account for about 3 per cent of the tumors of the stomach.

Sarcoma. Sarcoma of the stomach is not a common gastric neoplasm but must be considered in the differential diagnosis of tumors arising in this location. Fifty-one such tumors were noted in the group of 1700 gastric tumors. The reported incidence of sarcoma of the stomach varies. Ewing estimated that sarcomas comprised about 1 per cent of all gastric neoplasms. D'Aunoy and Zoeller found only 335 cases of sarcoma recorded in the literature through 1929.

Theoretically, sarcoma of the stomach may arise from any of the mesenchymal tissue components of the organ. Malignant sarcomatous tumors arising from the fibrous tissue, fat and blood vessels, however, are so rare that they are merely surgical curiosities. For practical purposes, there are two types of gastric sarcomas, those arising in the smooth muscle and those arising from

Table 2. Pathologic Classification of Malignant Neoplasms of the Stomach

1. Lymphoma (unclassified)
 - a. Hodgkin's disease
 - b. Reticulum cell sarcoma
 - c. Lymphosarcoma
 - d. Lymphocytoma
 - e. Macrofollicular lymphoma
2. Leiomyosarcoma

Figure 51 Reticulum cell sarcoma of stomach proved by exploration and biopsy. Marked deformity of entire media of stomach with coarsening of mucosal folds suggests lesion other than carcinoma

the lymphoid tissue elements. The pathologic classification is given in Table 2. The general term includes the malignant lymphomas and these may be subdivided according to histopathologic criteria laid down by Warren and Lulenski. The most frequent types of these tumors, however, are the lymphosarcomas and the Hodgkin tumors arising in the stomach. These localized lesions in the stomach may represent instances in which a primary focus of a generalized lymphoma is detected before widespread involvement is recognized. The tendency for malignant lymphomas to remain circumscribed in the gastrointestinal tract is commonly recognized. Malignant lymphomas may arise in any of the various segments of the gastrointestinal tract but occur most often in the stomach. Warren has reported that thirty out of forty-nine gastrointestinal lymphomas arose in the stomach.

The clinical behavior of malignant lymphomas of the stomach is similar to that of carcinomas occurring in this organ. The symptoms, in general, are those of gastric carcinoma, chiefly epigastric pain, simple indigestion and anorexia. The roentgenograms are usually diagnostic of a malignant lesion involving the stomach and the roentgenologic examination presents no characteristic picture on which a diagnosis of sarcoma can be made with any degree of certainty (Fig. 54). In a group of forty-one patients having sarcoma of the stomach, the preoperative diagnosis was made in only one subject in whom the tumor arose from lymphoid tissue, but was suspected in two other patients.

The only treatment of value in these patients with gastric sarcoma is radical resection of the stomach which, when the tumor arises on lymphoid tissue, should be followed by deep irradiation treatment. Sarcomas of

lymphomatous origin will respond to x-ray therapy, which should be used four to six weeks after resection, but x-ray treatment may also be effective in those tumors of lymphoid origin which are too extensive to warrant resection. One of our patients with Hodgkin's disease of the stomach, who had x-ray therapy only, lived seven years after exploratory operation and biopsy. Resection was not possible because the tumor was too extensive. Irradiation treatment should not be used before resection is carried out in those patients with suspected malignant lymphoma, since irradiation of a hollow viscus containing a large ulcerating tumor may entail the danger of gross hemorrhage and perforation. If at operation resection is not possible and biopsy only is done to determine the nature of the tumor, this risk of x-ray therapy must, of course, be taken.

The resectability rate for sarcoma is higher than for carcinoma and the five-year survival after resection is surprisingly good—44 per cent of our group survived five years or longer after resection.

Leiomyosarcoma. In a total of fifty-one sarcomas of the stomach, sixteen arose from smooth muscle to form leiomyosarcoma. These tumors, similar to the benign leiomyomas, exhibit a marked tendency to hemorrhage and thus produce marked secondary anemia and yet often they produce surprisingly little gastric distress, even though the tumor is large, unless rhage en-

sues. One such resected tumor weighed 2050 gm. Many of these sarcomas are resectable and the prognosis after resection is much more favorable than for carcinoma.

Leiomyosarcomas resemble the benign leiomyomas grossly and can be recognized only upon microscopic examination. There is no proof that any of the leiomyosarcomas arise from a pre-existing benign tumor. Pathologically, leiomyosarcomas arise from the gastric muscularis and are composed of spindle-shaped, relatively well-differentiated, smooth muscle cells in which scattered mitoses are present in each mass. The general impression is that these tumors are of rather slow growth and low grade of malignancy. They can be differentiated from the benign leiomyomas by evidence of invasion of normal tissue of more active growth. Invasion of blood vessels or lymph vessels is not found.

Leiomyosarcomas are considered to be slow growing and not prone to metastasize, they seldom recur after operation. We have noted metastatic lesions recurring in four patients with leiomyosarcoma, with metastasis to the lymph nodes, liver and the lungs. Results, in general, are good after resection of malignant smooth muscle tumors and, unless there is evidence of metastasis at the time of operation, cure can be expected. However, these lesions can metastasize and cause death. One patient who had a large leiomyosarcoma on the greater curvature of the stomach died of extensive metastasis to the liver. At post-mortem examination, the liver weighed 22 pounds and was almost completely replaced by tumor tissue. The primary growth also filled the entire left side of the abdominal cavity.

Irradiation treatment has no effect on sarcomas of smooth muscle origin.

Carcinoma. Carcinoma arising in the stomach is one of the most frequent forms of can-

cer in human beings and, similar to other forms of malignant disease, is found with greatest frequency in the older age group. It is estimated that 25,000 to 35,000 persons die each year in the United States from cancer of the stomach. It can be estimated further that approximately three or four times that number are alive with unrecognized disease or still living with diagnosed cancer, either inoperable or successfully resected. The Bureau of Vital Statistics in the United States in 1952 reported total deaths from cancer of the stomach to be 23,466. This is a slight decrease over previous reports and represents 10.5 per cent of the total number of deaths from malignant disease (Table 3). The total number of deaths from neoplasms of the stomach for 1954, 1955 and 1956 (Table 4) is approximately the same for these years. Ninety-five per cent of the carcinomas of the stomach occur in patients more than forty-five years of age and in the 1952 report from the Bureau of Vital Statistics, 92.2 per cent of patients were between the ages of fifty and 100. The age and sex distributions are shown in Table 5.

Pathology. There is no uniformity in the literature regarding the classification of gastric tumors. It is difficult to fit the microscopic features of a gastric carcinoma into a classification based on gross features. We use the classification as suggested by Warren and Meissner, which is based on histopathologic features alone, and we find this classification satisfactory for the clinician and pathologist in discussing malignant neoplasms which arise in the stomach (Table 2). The terms medullary and ulcerating are used in describing the gross characteristics and indicate gross changes noted in carcinomas. Linitis plastica is a carcinoma simplex with diffuse infiltration of the entire stomach wall (Fig. 55). Warren and Meissner have not attempted to grade tumors on cellular char-

acteristics because it is a difficult procedure and may vary with the individual pathologist. In their experience, the gradation of tumors has assisted very little in the prognosis of carcinoma of the stomach. In a group of 653 patients who had a probable curative resection, there appeared to be little difference in the five-year survival rate based upon the microscopic diagnosis of the tumor, except for those patients with mucinous adenocarcinoma.

Gastric cancer has a tendency to metastasize to regional lymph nodes, to exhibit a diffuse lymphatic spread in the gastric wall and also to show vascular invasion. This tendency to vascular invasion may have no relation to involvement of the lymph nodes or the lymphatic system, as pointed out by Meissner. Lymphatic spread may extend across the pylorus into the duodenum and has been noted 3 cm. distal to the pyloric vein. It may also involve the esophagus. Regional lymph node involvement is not uncommon and occurred in 61.8 per cent of 856 resected cases.

Carcinoma arising in the cardia along the lesser curvature has a marked tendency to involve the lower esophagus. There is also a tendency for tumors of the media to involve the lymph nodes of the splenic group, and tumors of the lower part of the stomach, even on the left lesser curvature, may show a strong tendency to spread to the lymph nodes of the splenic hilum. There is then a tendency to spread to the duodenum, esophagus and the regional lymph nodes. Moreover, a significant portion of the immediate lymphatic drainage from the stomach occurs into the peripancreatic tissues, which at

operation may be technically inseparable from the pancreas. Routine elimination of lymph nodes along the major vessels and omentum, as well as removal of the spleen, undoubtedly improves the cure rate.

Symptoms. The fundamental inherent weakness of methods for early clinical detection of cancer of the stomach is due to the fact that the disease may be asymptomatic until it has spread to adjacent structures or has metastasized through blood vessels and lymphatics. Early symptoms may appear only after the disease is surgically incurable and may be vague and nonspecific. In a recent analysis of the earliest symptoms noted in 1708 consecutive patients with carcinoma of the stomach, we noted the frequency of early symptoms (Table 6). Epigastric pain and discomfort, anorexia and vomiting were among the earliest symptoms. Thus, epigastric discomfort and pain are

Figure 55. Linitis plastica—diffuse carcinoma simplex. Specimen removed at total gastrectomy. Note marked infiltration of gastric wall.

very common early symptoms and, when persistent and progressive, demand early roentgenographic examination. Weight loss of some degree was noted in 90 per cent of patients. Great weight loss, severe anemia, vomiting, hematemesis and melena are evidences of advanced carcinoma and too often are manifestations of inoperable carcinoma of the stomach.

Diagnosis can be established early only upon the basis of suspicion of carcinoma on the part of the physician in all patients with indigestion beginning later in life, and in particular in the male past forty-five years of age. Patients who show evidence of weight loss and marked anemia without evidence of gastric obstruction should be carefully screened for the possibility of gastric carcinoma. Bleeding from a gastric carcinoma may be evidenced by vomiting blood or by

passage of black tarry stools (Fig. 56), but this is not as common as in benign ulcer and, again, occurs usually in advanced carcinoma.

Precursors of carcinoma. Earlier diagnosis will be made when the importance of the precursors, or the precancerous lesions of the stomach, is well recognized. Many observers agree that chronic gastritis may be a precursor of cancer of the stomach. Not all stages or types of chronic gastritis can be considered precancerous, but chronic gastritis occurring in the prepyloric or antral region should be carefully differentiated from tumors. Warren and Meissner have emphasized the fact that the epithelial and infiltrative changes which occur in the gastric wall in chronic gastritis could very well be the precursors of carcinoma. Gastric polyps should be regarded as premalignant lesions. In our experience, 30 per cent of the gastric polyps have proved to be malignant upon excision and microscopic examination. Clinical evidence seems to support the conclusion that approximately 10 to 20 per cent of gastric ulcers which appear benign grossly on roentgenologic and clinical examination prove to be malignant on microscopic examination. We should therefore be very suspicious of cancer in the so-called benign gastric ulcer.

We should be suspicious of cancer in patients who have a family history of gastric

Figure 56. Early adenocarcinoma in antral area of stomach in a man seventy-one years of age. The only symptom was melena.

Figure 57 Extensive adenocarcinoma of the distal half of the stomach. At operation, the cancer was found to be nonresectable because of widespread metastases. The tumor was palpable in the epigastrium.

carcinoma and in those individuals who are known to have achlorhydria of several years' duration. The incidence of carcinoma of the stomach in patients with pernicious anemia has been shown repeatedly in the literature to be three times as frequent as in other patients of the same age group. Laboratory tests, such as gastrosocopy, and roentgenologic examination should be carried out carefully in the patient with pernicious anemia.

Diagnosis. Early diagnosis is predicated upon the basis of constant suspicion of carcinoma as the source of epigastric distress in patients past the age of forty-five years, particularly in the male. Appropriate laboratory studies should be carried out at once and palliative treatment for gastric distress should not be employed until the possibility of the presence of carcinoma is definitely excluded.

Roentgenographic diagnosis in our group of patients with gastric cancer was accurate in 94 per cent of the group. Guiss, in a collective review of the end results of gastric carcinoma in 2891 patients, reported that x-ray examination was accurate in 90 per cent of the patients and in an additional 5 per cent the roentgenogram showed a gastric abnormality. Other laboratory procedures should be utilized when cancer is suspected. These include gastroscopic examina-

tion in patients with gastric ulcer, gastric polyp or chronic gastritis. Esophagoscopy should be employed in all patients with carcinoma involving the cardia in order to determine its extension to the esophagus, and involvement of the esophagus should always be suspected when dysphagia is present. The cytologic techniques of Papanicolaou are of value and, in some instances, early diagnosis may be established when the roentgenographic examinations fail to indicate the nature of the lesion. Other laboratory data, such as determination of gastric acidity and the red blood count, may assist materially in early diagnosis. Achlorhydria occurred in 36 per cent of our patients and free acid of less than 20 was noted in 18 per cent. Acid values, however, may be normal in many patients. Anemia may not be an outstanding symptom except in far advanced carcinoma, and hemoglobin and blood count determinations may be of value as diagnostic procedures only when marked anemia is present.

On examination, a mass may be demonstrated in the mid or epigastric part of the abdomen (Fig. 57). In a group of 1708 patients palpable tumor masses were noted in 516 patients, or 30.2 per cent. Too often this is evidence of advanced cancer. Large palpable tumors, however, may prove to be resectable at laparotomy and in 192 of this group of 516 they were resectable.

All tumors of the stomach, as evidenced by roentgenographic examination, must be considered to be carcinomas, since about 95 per cent of gastric tumors prove to be this type of lesion. A few tumors, such as leiomyomas or leiomyosarcomas and the polyp, show characteristic roentgenologic findings, but any intrinsic defect must be regarded as carcinoma until proved otherwise. Differential diagnosis, therefore, must be made of benign tumors, chronic gastritis and gastric polyp. The possibility of gastric carcinoma must be excluded in patients who have symptoms arising from diseases of the pancreas, gallbladder and colon. Digestive disturbances may result from disease arising in other organs, but, on the whole, the possibility of the presence of such diseases can be excluded readily by roentgenologic and gastroscopic examination. Cancer can usually be differentiated correctly from gastric diverticula by roentgenologic examination and diverticula rarely require any surgical procedure.

Bezoars, which are intragastric masses composed of hair (trichobezoar), vegetable

fibers and fruit seeds (phytobezoar), are encountered occasionally and may fill and form a complete cast of the stomach. In the majority of cases, the bezoar has a characteristic appearance roentgenologically.

Syphilis of the stomach is a very rare condition and, in view of this, every individual with a filling defect in the stomach should have an exploratory operation even though the Wassermann reaction may be positive and there is a definite history of gastric syphilis. We have seen gastric syphilis in a young man remain unchanged with intensive antisyphilitic therapy over a long period, the patient finally coming to laparotomy in order that the presence of cancer could definitely be ruled out. Gastric syphilis may resemble gastric carcinoma, the two diseases can occur concurrently and the most likely diagnosis to be made will be carcinoma. Valuable time should not be lost by waiting for the effect of antisyphilitic treatment in making the differential diagnosis.

Operability. In the light of our present knowledge, the only method of treatment for gastric carcinoma is removal of the tumor by partial or total resection of the stomach. The primary object of this is to relieve the patient of gastric distress and obtain a cure of the carcinoma, if possible. In patients with nonresectable tumors, surgical treatment may prolong life or alleviate suffering by a palliative procedure if the disease is not too widespread in the abdomen. The inevitable result of untreated carcinoma is 100 per cent mortality. We believe that all patients with gastric cancer should have the benefit of laparotomy when there is no definite evidence of extragastric spread which would preclude removal by surgical resection. During the physical examination preoperatively, the abdomen should be palpated carefully for a tumor and for the presence of an enlarged, nodular liver and ascites. Occasionally, extension of the tumor to the umbilicus will be found and in such subjects palliative operation is not advisable or helpful. Careful rectal examination with the patient in the knee-chest position should be made to rule out the presence of peritoneal implants in the pouch of Douglas. Enlarged supraclavicular lymph nodes, the nodes of Virchow, frequently indicate advanced cancer and operation is hopeless. If a Virchow node is present, a biopsy specimen should be obtained before any abdominal operative procedure is carried out. A roentgenologic examination of the chest should be made in all of these patients. If the various areas for

metastases of carcinoma are proved to be unaffected, exploratory laparotomy should be performed regardless of the size of the tumor and, in the majority of subjects, irrespective of the age of the individual. Operation can be carried out safely in the older age group provided the case is carefully evaluated preoperatively and the patient is properly prepared.

Operation. In a series of 1708 patients with carcinoma of the stomach observed at the Lahey Clinic from 1932 through 1954, the disease was considered to be too far advanced to attempt surgical resection in 810 and too advanced to attempt even exploratory laparotomy in forty-two. A total of 856 patients had resection and in 653 of these the resection could be considered curative. The term "curative resection" refers to a radical gastric resection, total or high partial, following which there is a reasonable hope of cure if all gross evidence of carcinoma is removed. We do believe, however, by employing exploratory laparotomy in all patients in whom metastasis cannot be demonstrated, a higher rate of resection will be possible without an appreciable increase in mortality.

Operative treatment of cancer of the stomach from the standpoint of cure consists of a radical partial gastric resection or total gastrectomy. The first successful partial gastric resection for gastric cancer was done by Billroth in 1881. The first successful total gastrectomy for cancer was done by Schilatter in Zurich in 1897. In the United States, the method used most frequently has been the Hofmeister modification of the Polya technique. This is an excellent method and permits high resection of the stomach with removal of all lymph nodes and the spleen. Reports of two important modifications of the Billroth II method were published in 1883 and 1889, the first by Kronlein and the second by von Eiselsberg. Von Eiselsberg closed the upper transected end of the stomach, thus reducing the size of the gastric orifice, and anastomosed the rest of the divided end of the stomach to the side of the jejunum. This method lends itself readily to radical partial resection of the stomach. These two procedures are often erroneously credited to Hofmeister and Polya, but were described by them in 1908 and 1911, respectively, at a much later date than were the descriptions of the operations by von Eiselsberg and Kronlein. The Hofmeister modification places the anastomosis anterior to the colon.

Figure 58 Distribution of lymph nodes of the stomach. Removal of all lymphatic drainage areas is part of a well-planned gastric resection.

Total gastrectomy should be employed in those patients whose cancerous process cannot be removed by any method short of a total removal of the stomach. Cancers arising in the distal half of the stomach or in the prepyloric region may be radically removed by a high subtotal resection. In view of the demonstrated metastasis to the splenic lymph nodes in many patients having gastric cancers, the spleen is removed in all patients subjected to partial or total gastrectomy. The omentum is excised completely, including the omentum between the spleen and the greater curvature of the stomach and also the gastrohepatic omentum, and, when partial resection is performed, only a small part of the stomach is permitted to remain, about 15 to 20 per cent. This more radical partial resection facilitates jejunal anastomosis, favorably affects the postoperative feeding problem and can be employed in many subjects rather than total gastrec-

tomy. All lymph nodes of the pyloric area, the celiac axis and curvature of the stomach should be included in the block dissection and the first part of the duodenum, almost to the level of the common bile duct, should be excised routinely. Removal of all lymphatic and vascular drainage areas (Fig 58) is of far greater importance than is the benefit to be obtained from total gastrectomy alone, although total gastrectomy will often be necessary if the cardia is involved or if extensive carcinoma is present. Diffuse gastric cancer, cancers extending high on the lesser curvature and those arising in the cardia necessitate total gastrectomy. Radical block dissection of all avenues of lymphatic spread is practically impossible, but routine elimination of the lymph nodes along the major vessels and the omentum will undoubtedly improve the cure rate. Total gastrectomy for the majority of patients with gastric cancer has not yet been shown to increase the five-year survival rate, on the other hand, it does produce problems of nutrition and of anemia as a result of the disturbed physiology. After total gastrectomy, many of these patients have considerable difficulty in obtaining sufficient caloric intake. Some patients, however, do very well after total gastrectomy if the physician constantly supervises the diet, nutrition and general hygiene and prevents the development of anemia.

Exploratory laparotomy carries very little operative risk and is the only method of determining whether the tumor is resectable or is so advanced that extirpation would offer nothing to the patient. If the tumor cannot be removed even by total gastrectomy, the best palliative procedure is partial gastrectomy. We believe that the ulcerating lesion can be removed safely with partial gastrectomy, that this procedure carries no higher mortality than does gastroenterostomy and that the patient has a greater opportunity to obtain relief of his symptoms by a palliative gastric resection. Total gastric resection should not be employed as a palliative operation unless there is a reasonable chance of removing all carcinomatous tissue. We ordinarily use a type of partial gastric resection, commonly known as the Hofmeister procedure (Fig. 59). The jejunum is brought anterior to the colon and the stomal orifice is made between a portion of the transected end of the stomach and side of the jejunum.

The Billroth I procedure (Fig. 60) is rarely used since a more radical removal of

Table 7. *Percentage of Total Gastrectomies in All Resections for Malignant Disease of the Stomach, 1944-1957*

the duodenum, together with radical partial resection of the stomach, is more practical by the Hofmeister method.

The relative frequency of employment of total gastrectomy versus partial gastrectomy in the Lahey Clinic is shown in Table 7. Gastric resection can be accomplished most satisfactorily in the majority of patients through an abdominal incision—an abdominal approach is used in 90 to 95 per cent of our subjects. A left transrectus incision is employed, extending from the costal margin caudally to just below the level of the um-

bilicus. The abdominal cavity can thus be explored and the decision made for partial or total gastrectomy (Fig. 61). If total gastric resection is deemed necessary, the incision can be extended and converted into a thoracoabdominal one by cutting across the costochondral arch into the fifth or sixth intercostal space. An incision of the diaphragm can be carried through the hiatus if a portion of the esophagus is to be excised. If desired and if, preoperatively, total gastrectomy is deemed necessary because of information obtained concerning esophageal

Figure 59. Hofmeister method of gastric resection, anastomosis is made anterior to the transverse colon

Figure 60. Billroth I, partial gastric resection

Figure 61 Abdominal incision for exploration and partial gastric resection. The incision may be extended to enter the left thoracic cavity by the division of the left costal margin, employed in total resection (Marshall, S F, and Uram, H Surg Gynec & Obst, vol 99)

involvement, a thoracoabdominal approach can be made through a low left thoracotomy incision (Fig. 62). The ninth rib is resected and the incision through the abdominal wall is extended in the direction of the thoracic incision by cutting the costochondral arch. In the hands of an experienced surgeon, the risk of exploration through the transthoracic approach is no greater than that through an abdominal approach. If resection proves to be possible, radical removal of the stomach can be carried out through the transthoracic approach and a more extensive excision of the involved esophagus can be performed. The mortality of total gastrectomy through a transthoracic incision is, perhaps, a little higher than when an abdominal incision is employed. Sweet reported fifteen deaths in a series of seventy-seven patients who had total gastrectomy through a thoracic or abdominothoracic incision.

When the abdomen is opened, the extent of the gastric tumor is determined and the abdominal cavity is carefully explored. If no distant metastases are demonstrated, the omentum is detached from the transverse colon and the lesser omental cavity is opened (Fig. 63). With the stomach elevated upward and with the omentum completely detached from the transverse colon, the lesser omental cavity and pancreas are widely exposed. Extension of the malignant process to the pancreas, the nodes of the

Figure 62 Thoracoabdominal incision for total gastrectomy, the ninth rib is resected, with extension of incision through the abdominal wall (Marshall, S F, and Uram, H Surg Gynec & Obst, vol 99)

celiac axis and to the mesocolon and colon can easily be determined and a decision made regarding operability. If the carcinoma of the stomach proves to be too extensive for resection, the operation can be terminated by dropping the colon and omentum back into the abdominal cavity. If resection is considered possible, the stomach is mobilized, the principal arteries are ligated and the duodenum is divided at a level just above the ampulla of Vater. All regional lymph nodes are carefully removed, the splenic artery just above the upper border of the pancreas is followed to the splenic hilum, and the splenic artery and vein are ligated just proximal to the left gastroepiploic artery. This will permit ready removal of the spleen and will control bleeding from the short gastric vessel. If it is necessary to proceed then with total resection, this may be done easily (Fig. 64). Thus, the stomach is almost completely mobilized following ligation of all the major vessels so that either a total or a high subtotal resection of the stomach can be carried out readily for removal of all of the tumor.

Table 8 Location of Gastric Carcinoma and Average Survival (Total Gastrectomy)

Diffuse	41	13.4
Total	—	—

If distant metastases are not found at operation, direct extension to adjacent organs does not prohibit resection of the left lobe of the liver and part of the pancreas and colon. The operative mortality has not been increased by
clude resectio

Operative n
ity in 127 patients having total gastrectomy at the Lahey Clinic over a ten-year period (1944 to 1953 inclusive) was 8.7 per cent, previous to 1943 the mortality was 31.6 per cent. The operative mortality for partial gastric resection likewise has been reduced to 3.2 per cent (1950 to 1951). The over-all mortality following operative procedures for gastric cancer is 5.7 per cent, this includes all types of operation—exploratory, palliative and partial and total resection.

In earlier years, the mortality in general was higher because of sepsis, which included peritonitis, mediastinitis and pneumonia. With the employment of chemotherapy and antibiotics, the operative mortality has decreased considerably during the past ten years in both procedures—total and partial gastrectomy. Good preoperative care with restoration of blood volume before operation and replacement of blood loss during operation has helped considerably in reducing the mortality in gastric surgery.

At the Mayo Clinic, the mortality rate following resection during the period from 1937 to 1949 showed a definite decline to a level of 8 per cent, which was about half that noted in 1937 (16.2 per cent). Wangen-

steen, in 1949, also noted that as resectability increased, the operative mortality of resection decreased over a period of ten years. McNeer and Pack reported that the operative mortality in total gastrectomy has been reduced from a high of 30 per cent to 11.4 per cent (1951).

Palliative treatment. Great relief of symptoms can be obtained by palliative procedures, among which partial gastric resection is most valuable. Gastroenterostomy may have to be used occasionally when the tumor is extensive and pyloric obstruction is present. We prefer partial gastric resection, inasmuch as an ulcerating tumor can be removed and this obviates further blood loss with its consequent anemia, relieves obstruction more effectively than does gastroenterostomy, is more effective in obtaining a good state of nutrition and adds considerably to the physical comfort of the patient.

X-ray therapy has not proved to be of great value as a postoperative measure in patients with advanced gastric carcinoma.

Figure 63 Exposure of the lesser omental cavity. The omentum is detached from the transverse colon and the stomach is elevated upward (Marshall, S. F., and Uram, H. Surg. Gynec. & Obst., vol. 99).

Figure 64 Total gastrectomy and esophagojejunostomy. The food pouch is made by employing a jejunojunctionostomy (Marshall, S. F., and Uram, H. Surg. Gynec. & Obst., vol. 99).

It may produce great discomfort, nausea and vomiting without materially affecting the tumor. It may be possible with the newer method, employing two million volt therapy, to obtain more effective palliation with this type of irradiation treatment, but to date, in a limited number of subjects, the results are inconclusive.

Medical treatment consists of drug therapy for relief of distress and pain. Sedatives will control early distress, but, eventually, as the disease progresses, opiates in some form will be required and should be given as needed. Constant supervision of a dietary regimen may be effective in alleviating or preventing much digestive distress, especially when drugs are added. Parenteral administration of fluids will do much to make the patient with advanced carcinoma more comfortable. Gastric lavage, using a Levin tube, also is helpful in patients with advanced disease in whom a palliative operation has not been possible. This insures decompression of an obstructed stomach with removal of retained food and other material.

Results of treatment. In the United States for the year 1956, the total deaths from cancer of the stomach numbered 22,119, of this number, 13,952 (63.1 per cent) occurred in males and 8167 (36.9 per cent) in females. By careful selection of all patients with gastric carcinoma, curative resection, either by partial or by total gastrectomy, can be performed in 38 to 41 per cent. Over a period of twenty-three years, 653 (39.2 per cent) of a group of 1666 patients have had curative resections and their course after operation has been carefully followed. In a smaller group of patients it will be possible to do a palliative operative procedure which helps materially in making the patient more comfortable but in most instances does not prolong the length of life.

The five-year cure after total gastrectomy for carcinoma of the stomach in our hands is 14.1 per cent, 26.2 per cent of the patients lived three years or longer. It must be remembered, however, that total gastrectomy has been employed heretofore only in those patients in whom the carcinoma was extensive and could not be resected other than by total resection of the stomach.

Of the group of 653 cases of cancer of the stomach in which resection was possible, the curability rate has increased notably. The five-year survival rate after resection has risen from 15.4 per cent for the patients operated on during the years 1932 through

1934, and from 29.7 per cent (188 resected cases) for the period from 1945 through 1949, to 39.5 per cent (76 resected cases) for those operated on during 1950 and 1951.

During this same twenty-year period (1932 through 1951) the ten-year survival rate after curative resection increased from 7.7 per cent for the years 1932 through 1934 to 16.6 per cent for those patients operated on during the years 1941 through 1945. For a group of 1708 cases in which a diagnosis of gastric cancer was made, whether or not resection was performed, the absolute five-year survival rate was 10.8 per cent. The survival rate after total gastrectomy in relation to the location of the gastric tumor is shown in Table 8. The survival rate with respect to the histopathologic state of the tumor is poor in patients with mucinous carcinoma, the average length of life of those who had resection being 14.9 months. The survival rate in patients with carcinoma simplex and adenocarcinoma was 21.6 months. The patients with adenoacanthoma lived an average of 34 months.

Carcinoma of the stomach can be treated surgically with a low mortality rate—3.2 per cent for partial gastric resection and 8.7 per cent for total gastrectomy.

The treatment of gastric cancer is not hopeless. The curability rate can be elevated by earlier diagnosis, through education of the public concerning the possibility of gastric cancer in those individuals who have persistent digestive distress, and by alertness on the part of the physician. Lowered mortality is dependent upon careful preoperative preparation, meticulous technique in gastric resection, the employment of antibiotics when needed, restoration of the volume and the chemical constituents of the blood to normal, and parenteral administration of fluids.

The Duodenum, Jejunum, Ileum and Appendix

By JAMES T. PRIESTLEY, M.D., and
EDWARD S. JUDD, M.D.

JAMES TAGGART PRIESTLEY was reared in Iowa because his grandfather, the fifth great-grandson of Joseph Priestley, went west after his graduation from the University of Pennsylvania in 1874. Educated in liberal arts and in medicine at the University of Pennsylvania, Doctor Priestley is a Mayo Clinic product in surgery and carried on his graduate work there. He is one of the members of the surgical staff at the Mayo Clinic.

EDWARD STARR JUDD, the son of a surgeon's surgeon, returned to his birthplace to practice his specialty. Educated at Dartmouth College and Rush Medical College, he received his surgical training at the Mayo Clinic where he is now a staff member.

THE DUODENUM

Lesions of clinical and pathologic significance in the duodenum other than benign ulcer are relatively uncommon. This fact may explain in part some of the differences of opinion regarding the incidence, diagnosis, clinical importance and treatment of such lesions. Certain of these abnormalities do cause definite and serious symptoms,

however, so it is essential that their presence be suspected clinically and that they be diagnosed accurately and treated properly if the patient is to have a satisfactory result. Others may represent an embryologic abnormality or a benign pathologic change which produces no hazard to life and perhaps no symptoms. Therefore, it is apparent that accurate evaluation of the findings re-

quires close cooperation between the internist, roentgenologist and surgeon if these lesions are to be properly diagnosed and if their proper clinical significance and appropriate therapeutic indications are to be determined.

To determine the type and relative frequency of lesions of the duodenum, other than benign ulcer, which require surgical treatment, a review was made of records at the Mayo Clinic for the years 1949 to 1953, inclusive. Table 9 lists the conditions for which operation was performed during this period. There were, of course, many additional patients on whom the diagnosis of some type of duodenal lesion was made but for whom operation was not advised.

Certain anatomic features are of importance to the surgeon. The duodenum commonly is spoken of as having three parts, namely, the first, second and third. Sometimes a fourth portion is described. The general conformation of the duodenum is that of the letter C or U, with some variation in the length and curvature of its parts. The first part, usually about 2 inches in length, extends from the pylorus posteriorly and to the right and lies to the right and above the head of the pancreas. The hepatic artery courses on the cephalic side and the gastroduodenal artery, common bile duct and portal vein lie behind this part of the duodenum. The first portion of the duodenum is commonly referred to by the roentgenologist as the duodenal cap or bulb. The second part of the duodenum extends for 3 or 4 inches and is directed vertically downward, with some concavity to the left in which lies the head of the pancreas. The common bile duct and the major and minor pancreatic ducts enter the posteromedial aspect of the midportion of the second part of the duodenum. Posteriorly, this part of the duodenum is usually in close relation with the right adrenal gland, kidney, renal ves-

Figure 65 Roentgenogram taken after the ingestion of barium. It reveals compression of the duodenum caused by carcinoma of the pancreas (Becker, J. W., and Kirklin, B. R.: *Am. J. Roentgenol.*, vol. 57).

sels and inferior vena cava. The third, or transverse, portion of the duodenum runs retroperitoneally for a distance of approximately 4 inches in a transverse direction at about the level of the third lumbar vertebra. Its anterior and inferior surfaces are covered by parietal peritoneum extending downward to the root of the transverse mesocolon and it is crossed by the superior mesenteric vessels and the root of the mesentery of the small intestine, in which those vessels are located. Therefore, it is apparent that, unless one is careful, examination of this portion of the duodenum may be difficult or incomplete in the usual abdominal exploration. In its terminal portion, sometimes considered as the fourth part, the duodenum ascends along the left side of the aorta and then turns forward to join the jejunum. At this point it is fixed by the ligament of Treitz, which is mostly a fibrous band but which may contain some muscle fibers.

Obstructive Lesions. Other than benign ulcer, a variety of causes exist for acquired duodenal obstruction. The clinical characteristics of these lesions and the indications for treatment naturally vary with the cause.

Acquired obstruction. Acquired obstruction of the duodenum, usually seen in adults, is most often caused by a malignant growth that arises near the duodenum, as in the pancreas, or by metastatic involvement of tissues adjacent to the duodenum, which in turn causes pressure on the duodenum (Fig.

65). Primary tumors of the duodenum may also cause obstruction. Inflammatory processes, reactions incident to foreign bodies, previous operation or some other intra-abdominal lesion likewise may cause duodenal obstruction. A nonspecific inflammatory reaction similar to regional ileitis occasionally may occur in the duodenum and cause disturbances in motility. Rarely, a granulomatous reaction may be encountered in the duodenum. Pancreatitis, pancreatic cysts, postoperative adhesions, post-traumatic hematomas and post-traumatic stenosis of the duodenum also have been reported as causes of duodenal obstruction.

In all such cases, the symptoms and findings of duodenal obstruction are present in varying degrees, although perhaps overshadowed by coexistent symptoms and findings. Appropriate treatment is determined after careful examination and evaluation of the patient. Operation often is advisable and its exact type usually can be determined only after the abdomen is opened and the true nature of the obstruction accurately assessed.

The diagnosis of "duodenal stasis" formerly was made with some frequency, but it is relatively uncommon at present. The patient usually presents a variety of functional symptoms, anorexia, belching and "fullness" in the upper part of the abdomen usually are noted. Roentgenologically the duodenum appears rather large, but no definite cause of obstruction can be demonstrated. The cause and treatment of such a condition appear rather uncertain, but the management should be conservative except perhaps in the extremely rare case.

Tumors. Primary tumors of any type in the duodenum are uncommon. If lesions which are not true neoplasms, such as a pancreatic rest, are excluded, probably the majority of tumors in the duodenum are malignant. The great majority of malignant tumors in the duodenum are adenocarcinomas. It has been estimated that approximately half of all primary adenocarcinomas of the small intestine are found in the duodenum. Ewing has stated that malignant tumors of the duodenum constitute between 2 and 3 per cent of all neoplasms of the gastrointestinal tract.

Benign Tumors. The commonest benign tumor of the duodenum is an adenoma. This may or may not present as a polyp (Fig. 66). Probably the most frequently found polypoid lesion in the duodenum results from protrusion of gastric mucosa through

the pylorus into the duodenum. Other benign tumors of the duodenum, all of which are uncommon, include myoma, leiomyoma, lipoma, hemangioma, fibroma, cysts, argenteaffinoma, fibroadenoma, fibromyoma and, if they are to be included in such a list, pancreatic rest and hypertrophy of the papilla of Vater. In most cases, lesions of this type are small, cause no symptoms and are discovered incidentally. Occasionally they may become larger, interfere with duodenal motility, possibly cause some obstruction of the common bile duct or bleed. The true nature of these benign lesions often cannot be determined with certainty without surgical exploration.

Management of lesions of this type varies with the individual patient. Some lesions are entirely symptomless and the roentgenologist is relatively certain that they are benign. Under these circumstances, especially if the patient is not a favorable candidate for a surgical procedure, it may be desirable to temporize and re-examine the patient in six or eight weeks. If the lesion has not changed roentgenologically at this time, operation again may be deferred and the patient re-examined in three or four months. In this manner, the benign nature of the lesion can be determined with further certainty and operation avoided. Periodic examination in the future over a period of years would be desirable under such circumstances. Should the lesion evidence increase in size, opera-

Figure 66. Benign polypoid tumor of the duodenum evidenced roentgenographically after ingestion of barium.

Figure 67. Carcinoma of the third portion of the duodenum. Note dilatation of the duodenum proximal to the lesion. This patient was alive and well five years after operation.

tion should be performed promptly. One always must be mindful of the possible development of malignant changes in an adenoma or a polyp and be guided accordingly in surgical judgment. In contrast, if the lesion causes symptoms or if the roentgenologist cannot be relatively confident of the benign nature of the lesion, exploration is advisable without delay.

At the time of operation for a tumor of the duodenum, the lesion should be examined and carefully inspected by transduodenal exploration. Its true pathologic nature should be determined by biopsy and immediate histologic study. If the lesion proves to be benign, simple local excision is all that is required.

Malignant tumors. Adenocarcinoma represents approximately 90 per cent of all malignant tumors found in the duodenum (Fig 67), although sarcoma and leiomyosarcoma and a few other types have been reported. Among patients who have duodenal malignant lesions, males predominate over females in a ratio of 2 or 3 to 1. Malignant tumors of the duodenum may be classified as supra-ampullary, periampullary or infra-ampullary. In some series, the periampullary group is said to be the largest, constituting 50 to 60 per cent of all lesions. However, it appears likely that, if lesions which actually arise in the ampulla of Vater are excluded, true primary duodenal malignant tumors

arise somewhat more often in the third portion of the duodenum than they do in either the first or second portion.

Most often symptoms caused by a malignant lesion in the duodenum appear gradually over a period of months. Four different types of symptoms may develop and direct attention to the lesion. These include those referable to duodenal obstruction, duodenal bleeding, duodenal perforation or obstruction of the biliary or pancreatic ducts. Obstruction may be the result of a polypoid or napkin-ring type of neoplasm and may cause variable degrees of crampy pain, vomiting and proximal dilatation of the duodenum and stomach. Bile may or may not be present in the vomitus, depending on the location of the lesion. Bleeding may be massive but often is slow and of the gradual oozing type, so that the patient may present himself to the physician primarily because of weakness and anemia. Perforation is usually gradual and may result in pain of the type associated with a penetrating duodenal ulcer situated on the posterior wall or with pancreatic neoplasm. Actually, pain of one type or another is the commonest chief complaint. Obstruction of the biliary or pancreatic ducts may result in jaundice or diarrhea or both.

A definite diagnosis usually can be made by a competent roentgenologist, although in describing the lesion he may use such

terms as "filling defect," "polypoid lesion" and "intrinsic lesion." Occasionally an extensive neoplasm, arising for example in the pancreas, may invade the duodenum secondarily and simulate a primary duodenal neoplasm. The presence of complete duodenal obstruction presents increased difficulty in accurate roentgenologic diagnosis.

Whenever possible, surgical removal is the treatment of choice for a malignant lesion of the duodenum. The surgeon must determine at the time of surgical exploration whether it appears possible to remove the lesion with some hope of cure, or whether involvement and extension of the malignant process are such that only some palliative procedure appears advisable. If the latter is the case, efforts should be directed to relieve symptoms as completely as possible with minimal operative morbidity and mortality rates. Various surgical procedures may be employed under these circumstances, depending on the findings. These techniques include duodenojejunostomy, gastroenterostomy, low gastric resection of the Billroth II type and cholecystenterostomy or some other type of anastomosis to relieve obstruction of the choledochus and perhaps also the main pancreatic duct. Irradiation has not proved of value unless the lesion is of lymphomatous origin.

If it appears possible that the growth can be resected with some prospect of cure, this, of course, should be done. Any operation performed for removal of a malignant duodenal neoplasm should embody the principles of operations performed elsewhere in the body for malignant growths. This usually entails a Whipple type of operation, with removal of the distal part of the stomach, the entire duodenum, the lower end of the common bile duct, the head of the pancreas and adjacent regions of lymphatic drainage from the duodenum. When the lesion is situated immediately below the pylorus, in the third portion of the duodenum, or at the duodenojejunal angle, resection of only a portion of the duodenum and its related regions of lymphatic drainage may be reasonable. Thus, an extremely extensive procedure with its attendant high morbidity and mortality rates may be avoided.

Diverticula. Diverticula probably occur more often in the duodenum than in any other part of the gastrointestinal tract except the colon. Among various adjectives used to describe duodenal diverticula are true, false, congenital, acquired, pseudo,

primary and secondary. Actually, two main types of diverticula are found in the duodenum; namely, the pseudo, false, or secondary diverticulum which results from contraction and deformity of the duodenum, most often because of long-standing benign duodenal ulcer, and the true duodenal diverticulum. The former type is commonly found in the first portion of the duodenum, immediately below the pylorus, and is most often apparent along the superior or inferior border of the duodenum as an outpouching situated just proximal to a zone of narrowing. Such an abnormality is not a true diverticulum.

The incidence of true duodenal diverticula is variously reported in the literature to range from less than 1 per cent to almost 6 per cent, as detected on roentgenologic examination (Fig. 68). Most necropsy data indicate a definitely higher incidence, which appears likely to represent a more accurate determination of incidence, since obviously not every diverticulum can be detected on roentgenologic examination, even by an expert roentgenologist. Careful studies at necropsy indicate an incidence ranging from 14 to 22 per cent.

Duodenal diverticula occur with equal frequency in both sexes. The largest number have been diagnosed in the sixth decade of life. They are uncommon prior to thirty years of age but have been found in the eighth or ninth decade of life.

Diverticula almost always are located along the mesenteric border of the duodenum. The reason for their occurrence in this region is commonly thought to be due to weakness in the muscular layer at the site where mesenteric vessels enter the intestinal wall. The wall of a duodenal diverticulum commonly consists of mucosa and muscularis mucosae; only seldom are other layers of the duodenal wall present. Diverticula vary in diameter from several millimeters to 5 cm. or even more. They are usually round but may be funnel shaped, bilobed or lobulated. Because of their location, they usually are imbedded in the pancreas, a fact which adds to the difficulty of their identification and treatment at the time of operation.

Most diverticula occur in the second portion of the duodenum, reported series describe 56 to 85 per cent of them in this location. Thus it is not uncommon to find a diverticulum in direct relationship with the common bile duct or a pancreatic duct, a fact which must be kept in mind in the sur-

Figure 68 Roentgenogram revealing a duodenal diverticulum. a, Soon after ingestion of barium. b, Delayed film showing retention of barium in diverticulum

gical treatment of such a lesion. Approximately 5 to 10 per cent of diverticula occur in the first portion of the duodenum and 20 to 30 per cent in the third portion. An occasional diverticulum has been reported in the fourth portion. Multiple diverticula occur in the duodenum in 15 to 30 per cent of cases, according to reports.

Usually pathologic changes are not associated with a diverticulum, however, inflammatory changes, infection, ulceration, perforation, hemorrhage, calculi and tumors have been reported. If, as is usual, the diverticulum has a relatively wide mouth and there is no retention within the sac, it is likely that the mucosa-lined cavity will evidence no pathologic change. If, on the other hand, the neck of the sac is small, retention may occur and infection, ulceration and associated changes may develop. A distended diverticulum may cause pressure on the biliary or pancreatic ducts and even obstruction of the duodenum has been reported, but all these complications are rare.

Most duodenal diverticula produce no symptoms. In the small percentage of patients in whom symptoms do occur, they are

not necessarily pathognomonic of a diverticulum. It must be decided whether these symptoms actually are caused by the diverticulum or by some associated lesion, such as peptic ulcer or cholelithiasis, or a disorder such as an irritable bowel or functional dyspepsia. The differential diagnosis is not always easy, but it is likely that the diverticulum should not often be incriminated. The most characteristic symptoms appear to be those of periumbilical pain, which may shift to the epigastrium or the right upper abdominal quadrant. The pain appears soon after meals and may be associated with a feeling of fullness or nausea. It may be relieved by belching or vomiting. Usually, if these symptoms are caused by a diverticulum, the roentgenologist can demonstrate retention of barium in the diverticulum. Diarrhea or constipation and loss of weight also have been reported but are of little diagnostic value.

It is generally agreed that only the exceptional diverticulum requires surgical treatment, which includes probably less than 5 per cent of those discovered roentgenologically. In the large majority of patients,

this abnormality is an incidental finding of little, if any, clinical significance.

In a smaller group of patients, there may be symptoms referable to the upper part of the gastrointestinal tract and careful investigation reveals no abnormal findings other than the diverticulum. The question then arises whether or not the diverticulum is the cause of the symptoms. Under these circumstances, appropriate medical treatment is recommended. This may consist of a bland diet, use of antispasmodics and alkalis and perhaps postural drainage or other procedures which appear to be indicated. Should the symptoms not be relieved, one then must determine if the evidence and symptoms appear to be sufficient to advise exploration with a view to operation on the diverticulum, if no other satisfactory explanation is found for the patient's symptoms.

In a recent study made at the Mayo Clinic, only thirty of 525 patients in whose records the clinician indicated the presence of duodenal diverticula underwent exploration of the upper part of the abdomen. Many duodenal diverticula incidentally discovered by the roentgenologist during this same time were not entered as diagnoses in the clinical records. In only eight of these 525 patients was duodenal diverticulum the main indication for exploration. Before deciding to proceed with an operation for duodenal diverticulum, the physician not only must exclude organic disease elsewhere in the abdomen which might be responsible for the patient's symptoms, and thus may require careful and thorough investigation, but he also must evaluate the magnitude and importance of the functional symptoms presented by many of these patients. Actually, evaluation and exclusion of the latter group of symptoms are usually the most difficult part of arriving at a decision regarding indications for treatment.

A few patients who have duodenal diverticula are explored surgically in an effort to relieve disabling symptoms. Careful exploration is essential to determine if there may be any other possible explanation for the patient's symptoms. If such a condition is found, it should, of course, be corrected. In the absence of other findings and without evidence of considerable certainty that incriminates the diverticulum as the cause of trouble, it appears advisable that surgical attack on the diverticulum should be undertaken only when the anatomic findings are such that operation on the diverticulum can be accomplished with minimal risk to the

patient. Often this is not the case because of close association between the diverticulum and the biliary or pancreatic ducts or its complete inclusion in the pancreas.

There remains the exceptional patient in whom it appears definite from the history and clinical findings, such as retention of barium in the diverticulum, partial obstruction of the duodenum or pathologic changes in the diverticulum, that the diverticulum actually is the cause of the symptoms. Surgical treatment may be indicated for some of these patients.

Because of the common location of a diverticulum along the concave border of the duodenum, the lesion usually is not apparent on initial exploration. Various procedures have been suggested to aid the surgeon to locate the diverticulum. Among these are previous ingestion of barium, which will present a whitish appearance through the wall of the diverticulum, injection of air into the duodenum to inflate the diverticulum and palpation of the neck of the sac with an exploring finger inserted into the duodenum through an appropriately placed incision for duodenotomy. Diverticula situated in the second, or descending, portion of the duodenum often are approached most satisfactorily by mobilizing the duodenum laterally and rotating it forward and to the left so that its mesenteric border is approached posteriorly. A diverticulum situated in the third, or transverse, portion of the duodenum requires mobilization of the retroperitoneal portion of the duodenum. Depending on whether the diverticulum is located in the proximal or distal portion of the third part of the duodenum, it may be approached best from the right or the left. It may be more accessible by exposure through the gastrocolic omentum or base of the transverse mesocolon.

When the diverticulum is located and exposed, one of various surgical procedures may be employed. Complete excision of the sac, with careful suture of its neck, is probably the procedure of choice when this can be accomplished without unwarranted trauma and hazard. Inversion of the sac into the lumen of the duodenum, with suture of the neck, may appear to be the treatment of choice in some subjects, however, this may require as extensive dissection as does excision of the sac. Surgeons who have employed this method have not reported subsequent difficulty caused by protrusion of the sac into the duodenal lumen. In the exceptional case, mere suture of the neck of

the diverticulum performed through a trans-duodenal approach has been employed, although this would not often appear to be the most desirable treatment. Anastomosis between the diverticulum and the jejunum has been performed in a rare case but is probably seldom indicated. The choice of surgical procedure is influenced by the existence of significant pathologic changes within the diverticulum.

One always must be acutely mindful of important adjacent structures in any operation for duodenal diverticulum. Exposure and catheterization of the common bile duct usually are advisable prior to dissection of a diverticulum located in the region of the ampulla of Vater or extending into the vicinity of the choledochus. Likewise, identification and protection of the pancreatic ducts are equally essential if these ducts are in close relationship with the diverticular sac. Acute pancreatitis, pancreatic necrosis or fistula may follow ill-advised dissection and trauma to the pancreatic parenchyma.

Should direct operation on the diverticulum appear to be unduly hazardous, one occasionally may consider some alternate procedure, such as duodenojejunostomy, low gastric resection with a Billroth II type of anastomosis and exclusion of the duodenum, or gastroenterostomy. Although complete and lasting relief of symptoms has been reported after operation for duodenal diverticulum, a favorable result is not always obtained.

Fistulae. Duodenal fistulae may be of two types: external, in which the duodenal contents drain to the outside, or internal, in which an abnormal communication is present between the duodenum and some adjacent structure.

Fortunately, an external duodenal fistula, which is always a serious or potentially serious lesion, is not seen as often today as it was in former years. It may result from trauma, such as a perforating wound, the unintentional application of a clamp to the duodenal wall during the process of removing an extensively diseased right kidney or other forms of trauma during the course of a difficult operation in the right upper quadrant of the abdomen. It may result from failure of a suture line in the duodenum to heal satisfactorily. An external duodenal fistula is seen most often after a gastric resection of the Billroth II type in which the closure of the duodenum does not hold and the stump does not heal properly. Many factors may contribute to leakage from a duodenal stump

after gastric resection; some of these are general in nature and others are local. A poor nutritive status, anemia, extensive neoplasia, serious inflammation and infection are systemic factors which may result in poor healing of a duodenal stump. The local factors include inadequate blood supply of the duodenal wall, insecure closure of the duodenal stump, excessive tension on the suture line or increased intraluminal pressure. It appears likely that the last-named factor is the most important one in the majority of cases. Increased pressure within the duodenal stump after gastric resection may result from some type of obstruction in the proximal jejunal limb or from obstruction where the proximal jejunal limb joins the stomach. Unrelieved gastric retention due to obstruction of the distal jejunal limb may also increase pressure within the duodenal stump. Obviously all factors, systemic as well as local, which might favor leakage from a duodenal stump should be assiduously avoided.

If leakage occurs from the duodenal stump after gastric resection, it most often takes place between the third and tenth postoperative day. If drains have not been left in place to permit ready access of duodenal contents to the exterior, severe pain develops in the right upper abdominal quadrant. This pain may become generalized over the entire abdomen and perhaps be referred to the right shoulder. Localized tenderness is pronounced and significant increase in temperature and in pulse rate is associated. Prompt treatment is indicated. Free external drainage must be established, the stomach kept empty by means of an indwelling tube and fluids and electrolytes replaced according to the losses and requirements of the individual patient. The abdominal wall must be protected from the digestive action of the duodenal contents. This last requirement may best be accomplished by insertion of an aspirating catheter that exerts constant mild suction in the drainage tract. Many different preparations have been suggested to protect the skin of the abdominal wall around a duodenal fistula. One such preparation that works well is Sebreech's ointment, a small quantity of which may be prepared by mixing the following materials: bismuth subgallate, 4 gm., cottonseed oil, 25 cc., zinc oxide, 50 gm., starch, 50 gm.; lanolin, 60 gm.

In addition to the necessary local measures in treatment of a duodenal fistula, general measures are also important. Antibiotic therapy is usually indicated. Every effort to

improve the general healing ability of the tissues must be made, including satisfactory replacement of fluids and electrolytes, blood transfusion and as high a caloric intake as possible, especially aimed toward increasing the intake of protein. Improvement in the patient's nutritive status occasionally may be best accomplished by administration of appropriate formulas through a small polythene tube which has been passed through the nose and on into the jejunum. Intravenous administration is, of course, necessary. Any attempt at early direct surgical closure of the fistula is not recommended, primarily because of the hazard and slight chance of success. Later efforts of this type may be advisable in some cases. In past years, the mortality rate associated with external duodenal fistulae after gastric resection has been high. This should not be so, as early recognition and prompt treatment, both local and general, should

Internal duodenal fistulae may be of various kinds. The commonest one occurs between the gallbladder and the duodenum, usually because of severe acute cholecystitis associated with stones and obstruction of the common bile duct or, more often, the cystic duct. Under these circumstances, the gallbladder becomes adherent to the duodenum, a zone of necrosis develops in the wall of

the gallbladder which then involves the duodenal wall in a similar process and a communication develops between these two structures, with discharge of contents from the gallbladder into the duodenum. Such a fistula remains patent if biliary obstruction persists but may tend to heal if obstruction is relieved. It usually causes no direct symptoms despite the opportunity for reflux of duodenal contents into the gallbladder. It is usually discovered on plain roentgenographic examination of the abdomen when air is seen in some parts of the biliary tract. It also may become apparent on roentgenographic study after the ingestion of barium when this medium is seen to enter the gallbladder.

A somewhat less common type of fistula may occur in a similar manner between the common bile duct and the duodenum (Fig. 69). Rarely, a duodenal ulcer may perforate into the common bile duct. Fistulae between the duodenum and the hepatic flexure of the colon or distal parts of the small intestine may result from a neoplastic process, usually arising in a structure other than the duodenum.

Other Duodenal Lesions. Odd and unusual lesions of the duodenum occasionally may be encountered. These include cysts, unusual adhesive bands, localized duodenitis, foreign bodies, cutaneous pancreaticoduodenal fistulae and functional disorders. Careful clinical investigation will help in the diagnosis in cases of this type and consultation among the roentgenologist, internist and surgeon should determine the course of treatment to be followed.

THE JEJUNUM AND ILEUM

Injuries of the Small Intestine. The surgeon may find himself in a dilemma concerning the possibility of injury to the small intestine, but in a large city hospital or an industrial region he may become expert in such a field. Even in a small community, he occasionally will be called to deal with the problem because of today's frequent automobile accidents. Even though no penetrating or perforating wound is present, a concussion type of injury to the abdomen may result in serious trauma to the small intestine. In some cases this is obvious and the general systemic signs disclose the necessity for surgical intervention. In other cases it is only by repeated close observation that the surgeon can make his decision.

In a gunshot wound, stab wound, or wound resulting from violence with a per-

FIGURE 69

forating type of instrument, examination may be easy and the conclusion may be reached quickly. The surgeon should not waste time by probing the wound, as he will not derive valuable information from this maneuver and merely may introduce more contamination. If the patient is seen in the early minutes after injury, his general condition may be most misleading and the surgeon must not be lulled into a false feeling of security. It is impossible to single out the small intestine alone because of the possibility of injury to other neighboring viscera, with physical signs and physiologic disturbances based on these concomitant changes. In addition, perforation of the small intestine occasionally may be obscured by partial or complete protection of the point of perforation by another viscus. Injuries to the abdominal wall produced by blows with a blunt instrument, crash injuries or crushing injuries will be most difficult to evaluate and the surgeon may be hard put to distinguish between extraperitoneal and intraperitoneal changes. The important factor is that the surgeon recognize the possibility of injury to the small intestine and make the error on the side of early interference rather than too prolonged observation. It goes without saying that the general condition of the patient is to be evaluated as to shock, hemorrhage and gross sepsis.

Laboratory findings vary, at times helpful findings may be numerous and at other times little or no aid is derived from laboratory studies. Determination of values for hemoglobin, erythrocytes, leukocytes and hematocrit may be of considerable help initially and of even more help if a period of observation is to be employed.

Roentgenologic findings may not be helpful at all in the early stages, as the changes will not have had time to develop. The presence of perforation accompanied by free air is obvious. Distention produced by paralytic ileus may be a relatively late sign, but it should always be looked for. In general, results of roentgenologic study do not change the surgeon's decision but occasionally give him additional information.

The treatment for injury to the small intestine is surgical. The surgeon first must place the patient in the best possible condition and this may call for heroic measures, as time is of such great importance. Shock can be treated efficiently today and the various types of fluids available for intravenous use all play a role. It is to be emphasized that no substitute exists for whole blood.

The passage of a gastric tube through the nose serves the dual purpose of emptying the stomach and obviating the factor of swallowed air later. In addition, the tube may be advanced manually through the upper portion of the small intestine at the time of operation should the surgeon feel this to be valuable.

The location of the incision may be dictated by local findings, but with the mobility of the small intestine it may not be as paramount as in other conditions. Small lacerations of the intestine may be sutured adequately, they must be made not only watertight but airtight as well. Large lacerations, multiple lacerations and disturbances of the mesentery demand resection of the intestine. The surgeon first must determine the complete extent of injuries to the small intestine, as he may waste valuable time repairing or resecting one segment and then find that a nearby segment demands the same treatment, whereas repair of both segments could have been included in one procedure. In earlier years, surgeons were forced to exteriorize the ends of the small intestine, but today this practice should be extremely rare indeed. Constant discharge of the highly irritating and digestive contents of the small intestine on the skin of the abdominal wall is something to be avoided if at all possible. The operation is not complete until thorough examination of all other abdominal viscera is carried out in an orderly fashion and the peritoneum is examined from within for small wounds or punctures which may have gone unnoticed.

In recent years, there has been a tendency to lavage the peritoneal cavity thoroughly before closure of the wound. This is a revival of earlier teaching. Surgeons are divided in their opinion as to the effectiveness of this maneuver, some of them consider that septic material may be disseminated in this fashion. A few years ago powdered sulfonamide drugs were dusted about the abdominal cavity, but this was largely discontinued because of the large dose that was administered at one time with irregular rates of absorption. It was difficult to know the exact level of drug obtained in the blood by this method; serious complications in the form of systemic reactions, plugging of the ureters with crystals of sulfonamide and other untoward phenomena led to general abandonment of the procedure. If injuries to other organs coexist and it is necessary to place drains in the abdominal cavity, substantial loss of the introduced

antimicrobial substance occurs. Various antibiotic agents have been placed in the abdominal cavity; however, it is now recognized that neomycin so administered may lead to respiratory failure. Thus, present opinion is that it is far better to administer properly measured doses of such agents in a parenteral fashion after operation.

When the patient is returned to bed after operation, there are many measures which the surgeon must keep in mind to bring about a satisfactory conclusion. The gastric tube should be attached to a suction device to maintain deflation of the upper part of the small intestine. This requires frequent attention, with checking of the suction and irrigation of the tube. Since nearly 70 per cent of the intestinal gas is swallowed air, the prophylactic effectiveness of a properly functioning tube is obvious. The tube should be kept in place until peristalsis has resumed a normal pattern and the patient is expelling flatus. Proper attention to fluid balance, with supply of the indicated electrolytes, protein supplements and vitamins, is rewarding. Blood transfusion is used as needed. Antibiotics are to be used liberally if a true indication exists. The surgeon will do well to be alert to the best possibilities for antibiotic support and above all to be alert to any possible serious sequelae of massive antibiotic therapy. With proper management, injuries to the small intestine may be controlled adequately with a generally good prognosis.

Infectious Diseases Involving the Small Intestine. Nonspecific infections. A vague and poorly defined group of symptoms, which, for lack of a better term, is often called "gastroenteritis" may cause confusion in differential diagnosis. Ordinarily, a properly taken history elicits possible exciting causes of the disturbance and serves to differentiate the condition. The presence of a mild epidemic in a family, community or region may be of significance. Unusual dietary factors, travel in places where sanitation might be open to question, and similar variations from a normal routine are important information for the surgeon to seek. Surgically, this poorly defined group rarely assumes much importance. The exact causal relationships of certain bacteria are open to some debate, as a variety of organisms can be recovered from the contents of the small intestine at different times. It is difficult to clarify why these organisms should be suspected of producing disease complexes at certain times and not at others.

Mesenteric adenitis is a fairly well-defined entity which has been recognized for many years. Its chief importance is its confusion with acute appendicitis. It is almost always at surgical exploration that the true nature of the condition is revealed. The symptoms are frequently those associated with acute appendicitis. The findings may be relatively mild, with tenderness over the abdomen, especially in the right lower quadrant. The presence of muscular spasm and pronounced localizing tenderness is unusual. It is difficult to explain why the findings should be more common on the right than on the left. The patient often exhibits mild fever and commonly is convalescent from an acute infection of the upper part of the respiratory tract. The patient often complains of nausea and occasionally vomiting; he is restless and may complain of "the grippe." At laparotomy, the appendix appears normal, but a striking feature is the extreme enlargement and engorgement of the mesenteric lymph nodes. Occasionally these masses will be of such proportions as to suggest lymphosarcoma, but in mild forms of the disease only moderate enlargement of a few of the nodes may be noted. Biopsy of these nodes and bacteriologic studies invariably result in a report of hyperplastic lymph nodes without specific pathogenic bacteria. In early years, the possibility of tuberculosis was considered and perhaps many patients were given that diagnosis without laboratory confirmation. The cause of mesenteric adenitis is unknown, although many factors have been suggested.

It is considered proper to remove the appendix at the time of laparotomy, as later confusion with appendicitis is thus obviated and it is considered entirely worth while to protect the patient by appendectomy. Recurrent attacks of mesenteric lymphadenitis have not been reported. It appears likely that recurrence is possible, but once the appendix has been removed the patient, or the parents, may never call the physician should a mild attack occur subsequently.

Specific infections. Earlier writings devoted considerable space to specific infections, in contrast to current articles, in which only passing mention of them is made. In a modern hospital in the United States it is extremely rare for the surgeon to be called on to assist in a problem of this type. In earlier years the reverse was true.

Typhoid fever characteristically strikes the lymphoid follicles in the small intestine, especially in the terminal portion of the

ileum Peyer's patches become the site of extreme ulceration, thus, in former years, surgeons occasionally observed general peritonitis on this basis. Laparotomy was necessary at times in desperately ill patients when perforation occurred, it is a matter of record that many of these patients recovered surprisingly well. At present, effective prophylactic and therapeutic measures are so general that the modern surgeon almost has forgotten typhoid fever. However, with travel made increasingly easy throughout the world, he would do well to keep it in mind.

Tuberculosis is another condition which was found to strike the small intestine on occasion. One suspects that at present the establishment of the diagnosis of tuberculosis is a much more scientific process than it was formerly and that many nonspecific granulomatous lesions of the intestine in past years were labeled tuberculosis. However, intestinal tuberculosis is still seen from time to time and the surgeon may be called on to resect the intestine because of the great obstruction produced by the contracture of the scarred tissues. The presence of pulmonary tuberculosis in these patients complicates the nursing care and the public-health problems involved. Fortunately, true tuberculosis of the intestine is extremely rare today.

Systemic Diseases and Their Relation to the Small Intestine. With increasing knowledge in roentgenologic techniques for study of the small intestine, the roentgenologist has become expert in detecting conditions which went unrecognized in earlier years. *Vitamin deficiencies*, especially those of the vitamin B complex, may occur with wasting diseases or faulty nutrition. The roentgenologist points out that he frequently can recognize such deficiency because the normal motility of the small intestine is greatly reduced. During fluoroscopy, he notices that the small intestine gathers its content of barium in irregular pools, which is a characteristic change. This is of importance to the surgeon, as the findings elicited and the symptoms presented by the patient might lead him to advise surgical intervention when the correct therapy would be entirely medical. Perhaps even more serious would be the error of failing to recognize the condition should it be complicating some other surgical lesion. The surgeon would do well to pay strict attention to the nutritional needs of the patient if time permits.

It is also probable that the small intestine may be involved secondarily in any *debilitat-*

ing systemic disease of prolonged duration and also in conditions associated with *complete lack of free hydrochloric acid* in the gastric contents because of the great speed with which the stomach empties into the small intestine.

Parasitic diseases may produce changes in the small intestine, their presence occasionally is disclosed by studies of blood smears as well as by systemic reactions. Of importance to the surgeon is the knowledge that *Ascaris lumbricoides*, the common round-worm, can produce a great degree of intestinal obstruction and he may be called on to relieve this condition surgically.

Although not exactly a systemic disease and admittedly rare, *gallstone ileus* should be mentioned. A previous history of cholelithiasis may be helpful, but it is not essential as "silent" gallstones may have been present. In this condition, intermittent severe ileus may puzzle the surgeon and the true nature of the lesion may be disclosed only at laparotomy.

Regional Enteritis. In 1932 Crohn and associates presented the first clear description of this disease. They pointed out that isolated cases similar to theirs had been reported for many years. The condition also has become known as "terminal ileitis" or "regional ileitis," with other similar pseudonyms being applied on occasions. It is a matter of some conjecture at present whether or not the incidence of this disease actually has increased sharply since 1932. It might be that tuberculosis was the diagnosis formerly assigned in many cases, but careful scrutiny of the literature suggests that an actual great increase in incidence may have occurred.

The changes are located characteristically in the terminal portion of the ileum. However, any part of the small intestine may be involved and we have observed cases in which the duodenum was the zone of primary involvement. One of the most ominous developments is the intermittent involvement of intestine in so-called skip areas, which indicates that the disease is of such a fulminating character that little of curative nature can be done for the patient. In chronic disease the changes in the terminal reaches of the ileum may spread into the right portion of the colon, which probably gave rise to confusion with tuberculosis in earlier years. A mass usually is present because of the granulomatous changes. The disease starts in the mucosa and, in its early stages, may be overlooked by the surgeon.

who examines the small intestine in a casual way. Later the thickening of the intestinal wall is extreme and the mesentery becomes tremendously broadened and infiltrated. The lymph nodes are greatly hypertrophied, which leads to considerable difficulty at the time of resection. Strictures of the intestine are commonplace and almost equally common is the formation of fistulae. These fistulae frequently extend to the cutaneous surface, as an unwary surgeon previously may have performed appendectomy because of a mistaken diagnosis. Fistulae involving other loops of small intestine, the colon and other organs, such as the urinary bladder, are common. The disease may be limited sharply to one region of the intestine, but the surgeon may have difficulty in determining just how far proximal the disease process actually extends on the mucosal side. Secondary changes are detected in the proximal part of the small intestine when constriction of the diseased segment has produced chronic obstruction, so that the proximal portion of the intestine is dilated and thick walled.

In a classic case of regional enteritis, the history is one of chronic disease. An acute form probably exists, but frequently a neophyte surgeon operates with a provisional diagnosis of appendicitis, finds a normal appendix and, after prolonged search, decides that the terminal portion of the ileum is a bit edematous and indexes the patient as suffering from "acute enteritis." This probably accounts for earlier reports of spontaneous cure and complete recovery without sequelae. True regional enteritis probably is irreversible and a properly taken history reveals that the patient has had difficulty for some time. Proper care should eliminate the necessity for emergency operations on these patients and thus sharply reduce the number of appendectomies done erroneously in this disease, with their associated high incidence of fistulae. The patient frequently is of Jewish extraction and often is in the second or third decade of life. However, patients of any race or age theoretically may be involved. Evidence of chronicity frequently is obvious. When the disease is in its advanced stages, the patient is somewhat emaciated and complains of diarrhea, cramps, attacks of intestinal obstruction, chronic loss of weight, anemia, repeated bouts of fever and, occasionally, hemorrhage. Formation of fistulae may be an important factor and, in addition to those mentioned above, the experienced proctologist may recognize the presence of perineal fistulae, which for some

reason are prone to appear in regional enteritis.

The diagnosis of regional enteritis is often suspected from the findings already mentioned. Routine hematologic studies disclose anemia in a large percentage of the subjects. Studies of stools eliminate parasitic infestations from the differential consideration. The presence of a mass is frequently reported and the patient may have been able to palpate the mass in the right lower quadrant for some years. He may state that during obstructive episodes the mass has ballooned up to a point at which it is easily visible on inspection of the abdominal wall. However, the ultimate diagnosis rests with the roentgenologist. The characteristic picture is that of the "string sign," caused by the pronounced constriction of a long segment of the intestine, the experienced roentgenologist can make the diagnosis with a great degree of accuracy.

The primary treatment of this condition is medical and every effort should be made to treat the patient in a conservative fashion. A bland diet free of foods high in residue should be the rule. Use of vitamin concentrates in liberal quantities helps to maintain a better nutritional state. Iron may be indicated to combat anemia. During periods of stress when diarrhea may be a large factor, codeine and paregoric may be used in liberal doses. Chemical agents, such as the sulfonamides, have been employed in large doses. The results have not been striking, but some workers consider that prolonged courses of sulfonamides may be of some benefit. All antibiotics developed up to the present writing have been entirely without effect on the disease itself, but secondary infections may respond to their use. With the advent of corticotropin (ACTH) and cortisone, it was only natural that these steroids should be tried in this disease. Opinion is somewhat divided, but reliable authorities have condemned use of these hormones in regional enteritis, as perforation of the lesion has been known to occur and severe hemorrhage has been reported as a result of their administration. Beneficial effects of these hormones have not been demonstrated in regional enteritis, aside from temporary production of a sense of well-being.

The surgeon will be called on to take over these cases when medical management does not suffice. Intestinal obstruction produced by the constriction demands surgical relief. Formation of a fistula is an obvious indication for surgical correction. Although most

of the patients are somewhat anemic, hemorrhage may not be a major factor, if it is, however, operation is to be seriously considered. The presence of an abdominal mass is not in itself a clear-cut indication, but it often demonstrates that a sufficient degree of obstruction exists to place the patient in a surgical category.

The type of operation is subject to some debate at present. In earlier years complete resection of all diseased intestine, along with removal of long segments of normal intestine in each direction with corresponding mesentery, was considered compulsory. A relatively high mortality rate soon demonstrated that a better method should be sought. In those patients in whom the lesion was considered inoperable because of extreme inflammatory changes, with attachment of the intestine to adjacent viscera and vital structures, it was found that short-circuiting or diverting types of operation had surprisingly good, even if temporary, effects. It was learned that a side-to-side ileocolostomy had little or no effect, but it is now common knowledge that excellent results may be obtained if the normal ileum above the diseased segment is divided completely and ileocolostomy is then done. Formerly, it was considered obligatory to re-open the abdomen at a later date, when the inflammatory change had subsided, and remove the diseased intestine. This is no longer the rule, as those patients who are progressing satisfactorily after a diversionary ileocolostomy may well be treated without later resection. In fact, some surgeons today consider that resection is not a good policy and leave the diseased intestine in place in most instances.

If the lesion is amenable to surgical treatment and is removable without the sacrifice of surrounding vital structures, it should be resected in a one-stage operation. If the operability is in question, we leave the diseased segment in place and short-circuit it by ileocolostomy after dividing the ileum. The patient is observed closely for several years to determine whether or not further operation is indicated.

With the widespread adoption of vagotomy for lesions of obscure cause, such as duodenal ulcer, it was only a matter of time before vagotomy was tried for ulcerative colitis and later for regional enteritis. The rationale for this operation in the management of enteritis remains obscure. Surgeons were reluctant to adopt it when they observed diarrhea in patients who had been submitted to vagotomy for peptic ulcer, hesi-

tating to make diarrhea even worse in patients with regional enteritis. Roentgen ray therapy has been administered to a few patients, especially those exhibiting recurrence after surgical resection. Not enough sound information has accumulated on the results to warrant more than its mention.

Enough patients with regional enteritis have been operated on and followed for sufficiently long periods for physicians to realize that the disease is fraught with a high rate of recurrence. Even the most radical operation has been known to fail to eliminate the disease in certain patients if a sufficiently long follow-up period has been observed. This had led some surgeons at present to become more conservative in their treatment. As already indicated, instead of putting the patient to the risk of an extremely radical resection, they are more prone to carry out conservative resections or even do mere ileocolostomy without an attempt at removal of the lesion. Complete removal probably is still the best choice, however. Recurrence at the site of anastomosis may be treated by further resection if indicated, and we consider that the development of "skip areas" in proximal segments some years after resection need not condemn the operation. The surgeon is well advised to look on regional enteritis as an extremely serious situation, since all manner of treatment may fail in more than 30 per cent of cases. Van Patter and associates have demonstrated that widespread optimism after any treatment is scarcely justified.

Tumors of the Small Intestine. Tumors of the small intestine are not common. Benign tumors (Fig. 70) include lipomas, myomas, fibromas, aberrant pancreas, polyps and hemangiomas. Many of them arise on the mucosal surface and it is only after prolonged growth that they give rise to symptoms. It is strange that the leiomyomas noted so frequently in the stomach occur so rarely in the small intestine.

Malignant tumors of the small intestine fortunately are rare. They usually are divided into three general groups, namely, adenocarcinoma, carcinoid and sarcoma. Primary adenocarcinoma has all the characteristics of this tumor seen in other glandular viscera (Fig. 71). Some of the patients with carcinoma of the small intestine are surprisingly young. The lesion is a vicious one, as diagnosis may be late, and widespread metastasis may be noted at the time the diagnosis is finally established.

Carcinoid of the small intestine is similar

Figure 70. Benign tumor of small intestine with obstruction and bleeding.

histologically to the same type of tumor more commonly located in the vermiform appendix. Carcinoids have been reported in the rectum and at other points in the intestinal tract. Carcinoid has been likened histologically to basal cell carcinoma. Many authorities have pointed out the argentaffin relationships exhibited and considerable debate persists as to the developmental background of these tumors. Frequently they present themselves as small submucosal growths which are characteristically yellow on cut section. They may extend around the circumference of the intestine to produce symptoms of obstruction. Numerous carcinoids often are scattered along the small intestine, but more commonly they are found in the distal part of the ileum. In contrast to the carcinoid of the appendix, that of the small intestine produces metastatic lesions rather commonly, not only in the regional lymph nodes but also in the liver. Hence the latter lesion is usually considered to be far more malignant than is the appendiceal tumor.

By far the commonest type of sarcoma encountered in the small intestine is lymphosarcoma. Studies of age incidence show that this tumor occurs in considerably younger patients than do other malignant tumors. Frequently it occurs as part of widespread disease so that other

tion may predominate, with an intermittent character to the syndrome since intussusception plays such a great part. Once the intussusception is reduced spontaneously, the patient may experience a long interval of relative comfort. The triad ascribed to obstruction of the small intestine, namely, intestinal colic, vomiting and distention, applies in advanced lesions. Melena is variable, depending entirely on the type of tumor. Frequently, the patient may be able to feel a mass through the abdominal wall, but this may vary considerably with peristaltic activity and the examining surgeon should not wait for such a finding if other factors are present.

The history may serve to confuse the sur-

Figure 71. Primary adenocarcinoma of small intestine.

made only by the experienced pathologist. The symptoms of tumors of the small intestine may be vague, so that considerable valuable time may be lost before a diagnosis is definite. As expected, symptoms of obstruc-

ion, but at times it may be most suggestive. Chronic intestinal obstruction often is the rule. The patient usually has lost considerable weight and may be emaciated. If definite severe obstruction is present, the usual roentgenologic findings are noted. If obstruction is not a dangerous feature, or is not imminent, the roentgenologist may employ x-ray and may be able to distinguish several varieties of tumor of the small intestine. This is a difficult field of roentgenologic diagnosis, however, and the surgeon should be satisfied if the roentgenologist merely verifies the presence of an indeterminate lesion of the small intestine. Anemia may be severe owing to chronic loss of blood and to serious derangement in the nutritional process. The anemia is often macrocytic, so that confusion may have been part of the picture early in the course when the possibility of a primary anemia might have been considered. The final decision rests with the surgeon, however, as the true nature of the lesion is rarely disclosed before laparotomy. A carefully elicited history, combined with certain cardinal physical and laboratory findings in the presence of an indeterminate roentgenologic report, leads the surgeon to explore the abdomen with good reason.

Resection of the intestine is indicated in the majority of benign tumors of the small intestine. Enterotomy with local excision of the tumor may suffice if one is satisfied that the resulting lumen at the point of repair is adequate. Frequently the surgeon accepts the risk of resection even in such a patient because of the possibility of postoperative obstruction otherwise. Radical resection should be done in malignant tumors, with removal of a large segment of mesentery. The method of anastomosis varies with the ideas of the surgeon, but an end-to-end union is satisfactory in most cases. Great discrepancy between the lumina of the two loops to be connected may lead to some modification of this anastomosis.

The prognosis depends entirely on the nature of the lesion. Benign tumors are permanently eradicated, but the outlook in malignant tumors is ordinarily rather poor. Distant spread often is present at the time of operation and palliation is all the surgeon can offer. The extremely malignant nature of some of these tumors means early recurrence in spite of what appears to be a very radical approach. Postoperative roentgen ray therapy is of great help in lymphosarcoma but in few if any of the other lesions. Even in

lymphosarcoma, the long-term results are disappointing.

THE APPENDIX

Appendicitis. Appendicitis is one of the commonest surgical lesions in the civilized world today. It is rather amazing to reflect on the length of time that was required before this disease was recognized fully and its seemingly simple treatment was accepted generally. It was not until 1886 that Reginald Fitz recognized the entity completely and it was through his publications and enthusiastic discussions that the medical profession at long last became aware of the true nature of appendicitis.

The gross appearance of the vermiform appendix is variable and its length appears to be of little significance. It is located at the tip of the cecum at the point of convergence of the taeniae, which at times is of convenience in locating it surgically. Much has been written about the possible positions of the appendix and even the most experienced surgeon may encounter difficulty in locating it, especially during a severe attack of appendicitis. Thus, the surgeon must remember that almost any location of the appendix in the general cecal region is possible, so that he may have to search down into the pelvis, along the great vessels of the abdomen, medially toward the sacrum, posteriorly, or actually among coils of small intestine. The appendix frequently is found in a retrocecal position and often appears to be retroperitoneal also. This only serves further to confuse the surgeon and at times makes proper recognition and removal a most difficult task.

Acute appendicitis may make its appearance at almost any age from the neonatal period to the period of most advanced senility. It appears to be more common, however, during the second and third decades of life. Most authorities state that it predominates in the male sex. It is most common among so-called civilized peoples. It has been suggested that dietary habits, rugged living associated with constant physical exercise, and bowel habits all have something to do with this incidence. People living in cities apparently are more commonly afflicted than are rural residents. Certain races, such as those in the Far East, appear to be relatively free of this disease.

The exact cause is largely unknown. Experimental appendicitis in laboratory animals cannot be classed as closely similar to naturally occurring disease in human beings.

and the difference in dietary and living habits is so great that an abnormal situation obviously obtains. Since the appendix represents a sac with only one opening, authorities agree that the "blind-loop" principle may be a factor. It appears that obstruction to the outflow of mucus and other contents of the organ is important. Indeed, in many patients with appendicitis, extremely hard fecaliths can be demonstrated in the lumen of the specimen. However, other specimens may contain multiple fecaliths with no evidence of any inflammatory change. It is difficult to assess the role of the bacteria within the intestinal tract since myriads of bacteria which do not appear to have much to do with this disease are constantly present. It appears, theoretically, that an inflammatory process would ensue if the mucosa of the organ suffers a rent, allowing a direct attack on the submucosal elements by the bacteria. Recurring bouts of appendicitis would be expected to lead to more serious attacks, since the resultant gradual occlusion of the ostium should further distend the remainder of the appendix. Kinking of the appendix by postoperative or postinflammatory adhesions should have much the same effect.

As already indicated, bacteriologic culture of the contents of appendices has yielded a multitude of organisms. One would expect to find *Escherichia coli* because of its natural habitat in the vicinity. Cultures in patients having appendicitis with perforation usually reveal several strains of streptococcus also. At present, routine culture in any patient in whom fluid or pus is found is considered valuable because of the more or less specific antibacterial agents now available. Many patients who have severe acute appendicitis exhibit cloudy fluid in the right lower quadrant which yields no organisms on culture. The surgeon can estimate the severity of the changes by observation of the fluid, especially by noting its odor. The familiar smell of an infection produced by the gram-negative bacilli commonly found in the colon is an ominous sign. Mixed infection is the rule in a gangrenous process with rupture.

The location of the appendix is important in determining what changes are exhibited during an inflammatory episode. It is convenient to think of appendicitis as starting as a simple inflammatory change of the so-called catarrhal variety involving the mucosa. This spreads to include all layers of the appendix. If allowed to go unchecked, the inflammatory change proceeds to gangrene and still further progression results in

perforation. Often the perforation is walled off by surrounding structures such as the small intestine, mesoappendix, large intestine and omentum. If the process of walling-off has not been effective, perforation leads early to generalized peritonitis. A word of caution should be sounded in that use of modern antibiotics may alter the inflammatory process considerably so that it may not follow any typical pattern.

The clinical picture in appendicitis adheres to no hard-and-fast pattern and even the most experienced surgeon must remember that he may be misled from time to time. Because the location of the appendix is so variable, appendicitis may simulate many other intra-abdominal lesions. The various stages of inflammatory change may confuse the picture, so that the only important consideration is to remember that the appendix may be inflamed and, on the basis of possibility alone, this diagnosis should be kept uppermost in mind.

The patient may note certain *prodromal features* which are gone by the time a surgeon is consulted. A feeling of malaise, followed by nausea, vomiting and general restlessness, often initiates the syndrome. These are such common symptoms that "gastroenteritis" may be the diagnosis and the patient and his family try to recall some dietary indiscretion leading to the temporary derangement. Abdominal pain may be relatively severe early in the course of the disease but may be so generalized that nobody thinks of the appendix. Frequently the patient states that the pain later centered about the umbilicus; this occurs so constantly that it bears repetition. Often at this time the symptoms appear to decrease in severity so that the surgeon may be caught off guard. Frequently, however, the pain shifts downward and to the right and although the nausea and vomiting, which may have been severe, now may tend to abate, the pain becomes the outstanding symptom. It may be colicky at first, but soon it becomes more constant in nature so that even the most uninitiated now thinks about the appendix. The patient assumes a position which gives maximal comfort, characteristically lying with the right leg drawn up and the knee flexed, and may refuse to straighten the leg.

At this point examination of the abdomen often is suggestive, as *tenderness* is present over the entire right lower quadrant, perhaps most pronounced at McBurney's point. However, in view of the variable location of

the appendix, this finding may not be at all reliable. The contact of the inflamed appendix with peritoneum is the exciting factor as far as tenderness and *muscular spasm* are concerned, but should the appendix be buried in other viscera these signs may be absent. One never must neglect to carry out rectal examination, and also pelvic examination in the female, as tenderness occasionally may be detected only by these maneuvers. The retrocecal appendix may lie directly on the right ureter and it is possible to have urinary symptoms secondary to this.

Fever is an unreliable sign. Gastroenteritis, or any similar upset, may be accompanied by fever, especially if vomiting is a factor and if dehydration is present. An increased pulse rate is too general a phenomenon to be ascribed to this disease. The restless patient who is experiencing more and more intense pain naturally has a fast pulse. However, a sustained rapid pulse, especially with an increasing rate, serves to stimulate the observer to reach a conclusion more quickly. *Leukocytosis* is always to be looked for routinely in attempting to make the diagnosis, but its importance may have been overstressed in the past. Intercurrent disease may be present which tends to increase the leukocyte count, but at times this determination is helpful. Many surgeons have seen severe appendicitis without much increase in the number of leukocytes. However, it is consistent to observe not only an increase in the total leukocyte count but a pronounced "shift" in their distribution, so that polymorphonuclear leukocytes predominate and evidence of an acute and overwhelming infection is clear cut. A blood count may be superfluous in a classic case of acute appendicitis. However, the clinical syndrome of appendicitis under present conditions may be confusing, with the widespread use of antibiotics, the process may be so thoroughly masked that the surgeon is hard put to make a decision.

It is obvious that the use of any form of catharsis during an illness which could have any possibility of being appendicitis is the grossest possible error. Rupture of the appendix has been observed far too frequently after the use of catharsis in such instances. Likewise, the administration of narcotics is looked on as poor practice, as the masking of the syndrome may make most difficult the decision regarding definitive care.

Several diseases may present symptoms which resemble those of appendicitis so

closely that differential diagnosis may be difficult.

Acute gastroenteritis is a poorly defined process and the term is used to include poorly understood syndromes. Dietary indiscretions, mild epidemic forms of diarrhea and vomiting and undue reactions to noxious substances are frequently classed in this manner. This is especially true if the patient is traveling in tropical or other countries which are radically different from his own with regard to food and drink. The prodromal symptoms of acute appendicitis may be practically identical to those of severe gastroenteritis and it is only by frequently repeated observation that the true nature of the condition will be disclosed. The development of definite localizing tenderness over the appendiceal region is the most important single sign and takes precedence over almost any other feature. Occasionally the two conditions may coexist, at which time it requires considerable courage for the perplexed surgeon to advise appendectomy in the face of what appears to be a severe medical problem. Ordinarily it is not too difficult to make the differentiation over a period of hours.

The differential diagnosis between appendicitis and *stones* in the *urinary tract* may be most difficult. Even though the stone may be lodged in the renal pelvis, the referred pain may be in the appendiceal region, so that considerable confusion arises. The wise surgeon obtains scout films of the region of the kidney, ureter and bladder, as well as excretory urograms if necessary. These studies occasionally save a patient from undergoing an unnecessary operation.

It is not common to mistake appendicitis for *pyelitis* or *cystitis*, but it has occurred. The general reaction associated with these infections may produce a somewhat similar picture. Fever, chills, leukocytosis, abdominal pain and tenderness may confuse the issue. Ordinarily, the differentiation can be made on physical examination, coupled with careful analysis of the urine. An inflamed appendix lying directly on the right ureter can produce not only urinary symptoms but also erythrocytes and leukocytes in the urine.

Many surgeons have made the mistake of

course described by the duodenal contents after leaving the perforated duodenum and passing along the right lateral abdominal

fossa. Usually, a past history of peptic ulcer helps the surgeon to decide and, if the signs of appendicitis are present, the one who considers the possibility of a perforated ulcer obtains scout films of the abdomen to search for free air under the diaphragm. Since the treatment of both conditions is surgical, confusion of these two entities may not be too serious a mistake, but the location of the incision, of course, is different.

Difficulty occasionally occurs in distinguishing between *acute inflammation of the gallbladder and of the appendix*. If the gallbladder lies low in the abdomen, this differentiation may be almost impossible. Conversely, an acutely inflamed appendix high in the abdomen may be misleading. Past history of disease of the gallbladder is most helpful. Frequently, acute gallbladder colic subsides in a relatively short period. The extension of cholecystic pain to the back and the scapula may be of great importance in making a diagnosis.

Pelvic conditions do not play the prominent role they did in the days before the availability of complete antibiotic and chemotherapeutic programs. For a time, *acute salpingitis* defied even the most alert surgeon when it came to distinguishing it from appendicitis. The history is usually unreliable and the common factors of the two diseases, such as fever, leukocytosis and gastrointestinal symptoms, merely serve to cloud the issue. Pelvic examination often helps, since motion of the uterus produces extreme tenderness in pelvic infection and the tenderness usually is bilateral. The presence of gonococci in vaginal smears is suggestive but not conclusive evidence in attempting to rule out appendicitis. It is now uncommon for surgeons to explore the abdomen for appendicitis and find salpingitis to be the true diagnosis. The so-called *twisted ovarian cyst* remains a relatively common phenomenon and gives rise to many local signs suggesting appendicitis. Often the history and pelvic findings serve in the differential diagnosis, but occasionally laparotomy is the deciding factor. Since operative treatment is indicated in either event and the location of the incision is similar, no great mistake is made. More rarely, a pedunculated uterine fibroid may become twisted on its pedicle and produce a similar clinical picture. Another gynecologic condition which might suggest appendicitis is rupture of a graafian follicle. This normally appears about midway in the menstrual cycle and the pain associated with it is commonly referred to as

"mittelschmerz." Pain, fever and leukocytosis identical with the findings in appendicitis may be present. A similar picture is occasionally observed when a corpus luteum ruptures at about the time of onset of the menses.

Many other abdominal conditions may produce syndromes suggesting appendicitis. These are almost too numerous to list, but the chief factor is to keep the possibility of appendicitis in mind and to be alert for variations. *Mesenteric adenitis* may be the underlying cause of a syndrome similar to that of appendicitis. The patient's symptoms, physical findings and laboratory data may be identical with those of the patient having appendicitis. Frequently, a recent respiratory infection may be helpful in suggesting to the surgeon that lymphadenitis is the true diagnosis. However, it is only at operation that the distinction can be made and, as already pointed out, it is considered entirely proper to remove what appears to be a normal appendix in such a condition, thus ridding the patient of the likelihood of further difficulty. For the sake of completeness, one must include *acute inflammation of Meckel's diverticulum*. The picture can be exactly that of appendicitis, in fact, if the surgeon is removing what appears to be a relatively innocuous appendix, he should trace the small intestine for some distance searching for Meckel's diverticulum, inflammation of which may have given rise to the clinical signs. Diverticulitis of the sigmoid, ruptured ectopic pregnancy and acute hemorrhagic pancreatitis are all conditions which can be mistaken for appendicitis.

Abscess formation may be a complication of appendicitis. The abscess may depend on the location of the appendix, but occasionally one sees an abscess of alarming proportions whose walls are made up of viscera at some distance from the appendix. It may be impossible to state where a given abdominal abscess arose, since the fallopian tubes, the sigmoid and other organs within the abdomen may be the original source of the abscess and the findings may be identical.

With escape of noxious intestinal contents into the peritoneal cavity, *peritonitis* is the inevitable result. If Nature is successful, the peritonitis is localized so that a small abscess may eventuate. A dreaded complication, however, is one of widespread abdominal contamination. In this situation, the patient is in extremely serious straits, with generalized abdominal tenderness and rigidity. The drawn, anxious appearance of the face,

the pronounced abdominal distention and the complete lack of normal peristalsis make the dire situation evident to all examiners. This complication was common in earlier years and accounted for the high mortality rate.

One of the commonest causes of *subphrenic abscess* is gangrenous appendicitis with rupture. If the appendix is in a retrocecal position, the pus can burrow up behind the right portion of the colon to contaminate the entire subphrenic space. The possibility of a subphrenic abscess should be considered in any patient who is not recovering properly after prompt management of a ruptured appendix. If one waits until the roentgenologic findings are definite, valuable time will have been lost. If subphrenic abscess is kept in mind and is sought surgically at an early date, dire consequences can be averted.

In earlier years *pylephlebitis* was almost uniformly fatal. Its presence should be suspected when a patient with appendicitis, especially of the gangrenous variety, later experiences shaking chills and fever of the septic type. When suppurative thrombosis develops within the portal vein, the liver enlarges and the chills and fever continue unabated, frequently intensifying as time goes on. Jaundice becomes evident within a matter of days. Fortunately, the modern therapeutic adjuncts to surgical care have served to reduce sharply the incidence of *pylephlebitis*.

The surgeon is frequently surprised when operating at some interval after rupture of an appendix to note the paucity of adhesions within the abdomen. However, it is always possible that extensive adhesive bands will be the sequel after such a septic change, especially if several operations have been necessary. Many months or even years after operation, such patients may exhibit signs of definite obstruction requiring surgical relief.

The only treatment for acute appendicitis is surgical intervention. This disease presents a true surgical emergency and nothing but disaster will accompany delay. In general, several varieties of appendicitis may be encountered. The surgeon must decide for himself which type is present. Experience is the only guide in making a decision. In acute appendicitis, and rupture, the appendix produces uniformly excellent results. A second type of appendiceal disease is encountered when a definite abscess has formed and surgical con-

sultation has been sought late. A difference of opinion has existed in the past as to the proper management of such patients. For some years it was considered good practice to hospitalize the patient and keep him in bed until the abscess drained itself spontaneously, which it did in a great number of patients by bursting into the colon. Occasionally it pointed through the skin of the abdominal wall and ruptured externally. A change has occurred in surgical thinking which appears to be much better from the patient's standpoint. If the patient can be put into reasonable physical condition by use of the adjuncts now available, surgical drainage of the abscess is indicated. Often the appendix may be removed at the same time but should this entail considerable dissection, with the threat of injury to surrounding structures, such removal should be postponed. Two months should be allowed to elapse and, if the patient is in good condition at the end of that time, a second operation is in order to remove the appendix. It may be surprising, indeed, to note when an extreme local change has been brought about during that time and the appendix usually can be removed with ease. It is considered compulsory eventually to remove the appendix of these patients because repeated rupture is not at all rare.

The third type of appendiceal disease is that in which *general peritonitis* already is present. It is in such cases that the ingenuity and judgment of the surgeon may be taxed to the limit. He will do well to pool his knowledge with that of other observers so that the proper time for operation may be selected. Evidence of spreading peritonitis demands immediate intervention. In former years, evidence that the infection was being localized usually meant that the surgeon should allow more time to elapse. With the present help from all possible sides, the surgeon has considerably more latitude and can operate under more nearly ideal conditions so that the prognosis for the patient is considerably better than it was previously. He may remove the appendix of such patients and adhere to those general criteria which guarantee the safest possible course.

In simple acute appendicitis, no elaborate preparation will be necessary and early operation will be the only feature. When the disease is in a more advanced stage, the surgeon can take a few steps to assure more nearly optimal conditions. Dehydration may be overcome quickly by intravenous administration of properly selected fluids. Cher-

cal studies of the blood indicate what elements should be replaced. Lavage of the stomach is easily accomplished and may obviate the sequelae of tracheal aspiration of gastric contents which otherwise might occur should the patient vomit during or after anesthesia. The gastric tube may be left in place so that suction applied to it will be of considerable help in the removal of swallowed air and gastric secretion early in the postoperative period.

It was formerly common to insert antimicrobial substances into the peritoneal cavity at the time of operation. This procedure largely has been abandoned, as the dose is uncertain and rapid absorption might ensue with dire consequences. It now appears better to avoid intraperitoneal medication and give proper postoperative doses of the antimicrobial substances parenterally. The question arises concerning establishment of drainage in these subjects. Obviously no reason exists for drainage in acute, uncomplicated appendicitis. When a well-recognized abscess is present, with definite collection of pus, adequate drainage must be established. Several types of ingenious drains are available to which suction may be attached; their use has facilitated the care of these patients. The real question arises in general peritonitis. In such patients, it early became the rule in many medical centers to close the wound tightly without drainage. Occasionally peritonitis went on to fatal issue because drainage had not been established. Many authorities point out that in general peritonitis it appears rather futile merely to place several drains in the right lower quadrant, as they hardly could be expected to accomplish a great deal. The use of several soft-rubber tubes for several days would appear to be harmless, but considerable question is now raised as to their effectiveness. More recently, some authorities have argued for tight closure of the peritoneum and fascia, a drain being placed just at the level of the fascia and brought out of the wound.

In patients with simple, uncomplicated cases, postoperative care may be no problem whatsoever. The patient is allowed to get out of bed as soon as he wishes, peristalsis soon resumes its normal action so that alimentation returns to normal at an early date and the patient is dismissed within a matter of several days. In the presence of abscess, however, considerable attention must be directed to the wound and the proper care of the abdominal wall. Judicious

use of properly selected antibiotics based on sensitivity tests carried out on organisms obtained by culture of material taken at the time of operation speeds the healing process. However, when the abscess is well walled off and has been drained properly, use of antibiotics actually may be superfluous. In such patients, the establishment of normal alimentation depends entirely on the resumption of normal peristalsis. The condition of the wound dictates the activities of the patient and the proper course to follow.

Postoperative care in general peritonitis serves as a challenge to the surgeon. The importance of fluid balance already has been stressed and this must be maintained in detailed and conscientious fashion. Repeated transfusion of blood may spell the difference between success and failure. The maintenance of proper suction on the indwelling gastric tube is most important. In the face of severe paralytic ileus, it may be difficult to pass a Miller-Abbott tube through the pylorus and into the small intestine, but if this can be done it serves to combat the distention better than any other single factor. Certain surgeons now use catheter gastrostomy in preference to the employment of indwelling nasal tubes. Use of antibiotic therapy is dependent on scientific rather than wishful thinking. Tests of sensitivity performed on the organisms found to be present at the time of operation dictate which antibiotics to use. A word of caution must be sounded with regard to antibiotics lest their indiscriminate use produce complications just as serious as is generalized peritonitis. It is only after peristalsis begins to resume its normal activity and flatus is being expelled by rectum that the gastric tube may be clamped intermittently and, if the patient tolerates this well, later removed. A liquid diet is given cautiously and increased until a full diet may be taken.

Definite progress has been made so that at present the prognosis in almost any case of appendicitis is excellent. The concentration in recent years has been on the complications of appendicitis and such strides have been made that the surgeon today faces the problem with considerably more confidence than he did in earlier years. However, in spite of all the recent advances, there is no substitute for sound clinical judgment tempered with reason and based on frequent, accurate and consistent observations made at the bedside, with correlation of all the clinical phenomena as they are revealed.

Chronic Appendicitis. Perhaps little should be said about the so-called entity of chronic appendicitis. No one has been able to prove whether or not such a condition exists. It is obvious that repeated attacks of acute inflammation in the appendix may leave local sequelae and certainly the surgeon is well justified in such a patient in removing the appendix during a so-called quiet interval. It is always better to make the error on the side of surgical aggressiveness because prevention in such instances is worth far more than a pound of cure. However, the patient who presents himself with a collection of vague symptoms and a great lack of signs, complaining of fatigue, nervousness, excessive gas, constipation and indigestion, probably should be looked on as a constitutionally inferior person and it is better not to draw attention to the appendix without some definite reason. It is well known that appendectomy in such persons is fraught with a high degree of failure when judged in the light of relief of presenting symptoms.

Tumors of the Appendix. True tumors of the vermiform appendix are rare. They may be either benign or malignant. The commonest form is not a neoplasm but a condition known as *mucocoele*, in which the ostium of the appendix becomes occluded and the continued secretion of mucus by the glands within the appendix results in a characteristic mass that is easily recognized grossly. Removal of the appendix cures the condition. In greatly advanced lesions, the *mucocoele* may rupture, spilling its contents and the secreting cells into the free peritoneal cavity. As the process subsequently continues, the condition known as *pseudomyxoma peritonei* (jelly belly) results. Malignant *mucocoeles* have been reported.

Carcinoid tumors of the appendix are not

common but are rather characteristic when found. A firm mass is noted which on microscopic study shows a glandular picture. Many aggregates of tumor cells are buried in the submucosal layer; as already noted, the appearance has been likened to that of basal cell carcinoma, hence the origin of the term *carcinoid*. It is possible that these cells are of chromaffin origin. As has been mentioned previously, the small intestine can give rise to a similar tumor, where it is prone to characteristics of malignancy and is capable of metastasis. *Carcinoids* of the appendix remain localized and once appendectomy has been performed further trouble usually does not occur. A correct preoperative diagnosis is almost unheard of, the lesion being discovered incidentally.

True *adenocarcinoma* of the appendix is extremely rare. The surgeon may not know for some days after appendectomy that a malignant lesion was present. Since these are true cancers they should be treated as such. With the low risk to the patient of right hemicolectomy at present, it is well to submit the patient to this procedure once the diagnosis is established.

The Colon

By CLAUDE E. WELCH, M.D.

CLAUDE ENLISON WELCH is a Nebraskan whose father spent most of his early life teaching school. This fact may have influenced his son, a graduate of Doane College, a small college in Nebraska, to teach chemistry and obtain a graduate degree in organic chemistry at the University of Missouri. He received his medical education and surgical training at Harvard University and Massachusetts General Hospital. His surgical interests have been centered upon various phases of gastroenterology.

SURGICAL ANATOMY

The colon is defined anatomically as that section of the large intestine which extends from the ileocecal valve to the rectum. The lower level is difficult to identify accurately and the indefinite term "rectosigmoid" often is used to describe this junctional area. It is more accurate to employ Gilchrist and David's terminology. They divide the rectum into an extraperitoneal portion, located entirely below the peritoneal floor, and an intraperitoneal division which extends from the lower portion of the peritoneal reflection to the level of the third sacral vertebra. Above that level the bowel is no longer fixed and the true colon begins at the spot where this mobile mesentery is noted. Since the entire rectum is approximately 15 cm in length, about 10 cm of the terminal colon can be visualized through the ordinary 25-cm. sigmoidoscope.

The colon is subdivided loosely into the right, transverse and left portions. It is frequently better to employ more specific terms, so that from the proximal end these divisions become the cecum; ascending colon; hepatic flexure, proximal, transverse and distal transverse colon; splenic flexure; descending colon and sigmoid colon.

The arterial blood supply is furnished by the superior and inferior mesenteric arteries. Usually anastomosis between these two systems is maintained by the marginal artery which skirts the inner margin of the colon. However, short sections of this artery may be absent, particularly in the sigmoid and ileocecal areas, so that caution is necessary at the time of any operative procedure. Us-

ally the right colon is supplied by the ileocecal and right colic branches and the transverse by the midcolic, which arises from the superior mesenteric. The left colon is supplied by the left colic and sigmoid branches of the inferior mesenteric. The most common variations of this pattern include absence or an abnormal origin of the right colic branch. The left colic artery also may arise from the superior sigmoidal artery.

Venous drainage corresponds to the arterial supply and runs by way of the superior and inferior mesenteric veins through the portal system. Hence, blood-borne metastases from cancer nearly always appear first in the liver, though, later, collateral channels may involve the systemic circulation. The lymphatic drainage follows the arterial supply closely.

PHYSIOLOGY

While the colon is primarily an excretory tube, it also has absorptive powers. Water and electrolytes are reabsorbed, particularly by the cecum, so that the consistency of the fecal discharge is changed completely in this portion of the bowel. Glucose and sucrose are absorbed by the rectum and colon. Normally the colon secretes only mucus, although small amounts of some metals, such as bismuth and arsenic, may be excreted directly by the colonic mucosa.

HISTORICAL ASPECTS

Modern surgery of the colon has developed within the course of the last sixty years. Prior to 1800, sporadic cures of intestinal obstruction had been obtained by vari-

ous means such as the forcible injection of enemas or the administration of mercury by mouth. Multiple percutaneous punctures of the distended bowel occasionally prolonged life.

In 1710, Littre, a French surgeon, first suggested that a colostomy might be useful to relieve obstruction of the colon. However, it was not until 1776 that Pillore first successfully performed a cecostomy; the patient died a month later. In 1793, Duret first had a patient recover from a sigmoidostomy. After anatomic studies in 1839, Amussat found that a colostomy in the left lumbar area could be made without entering the peritoneal cavity and advised its routine use for cancer of the rectum.

The next stage in the development of colonic surgery involved the actual extirpation of a cancer of the rectum. Early surgeons resected the rectum, leaving an uncontrollable perineal colostomy. Lisfranc carried out the first successful operation in 1826, while Kraske added an excision of the coccyx and part of the sacrum in 1885. In 1833, a patient of Reybard survived after a resection and anastomosis for cancer of the colon. In 1879, Billroth resected the sigmoid colon and brought out the proximal end of the bowel as a colostomy opening. Thereafter, surgeons followed two separate modes of attack on cancer of the colon. The first involved resection and primary anastomosis. The mortality rate for this operation was high and was not reduced significantly by the introduction of Murphy's button type of anastomosis in 1892. It was not until 1908, when Parker and Kerr introduced the principle of aseptic anastomosis, that this method again became safe. However, the operation of resection and immediate anastomosis was not accepted widely until recently, but now has been adopted generally. That this procedure is unwise in the presence of acute obstruction was appreciated at an early date and Gibson's method of cecostomy (1902) was used widely to decompress the distended colon before resection was undertaken.

Meanwhile, the second trend in surgery of the colon involved the exteriorization of the obstructing lesion and its resection outside the abdominal wall. Thus, the death rate from peritonitis was practically eliminated. Bloch (1892) and Paul (1895) independently developed this method that was popularized by Mikulicz (1902). The same technique was modified and extended by Rankin (1930) and was for many years the

most widely accepted and by far the safest of the resections. Now, however, it has been nearly entirely replaced by resection and primary anastomosis, except for traumatic wounds of the colon, for which exteriorization is usually the treatment of choice, or for some instances of perforation secondary to diverticulitis or cancer.

WOUNDS AND INJURIES

The colon is particularly likely to be injured by missiles that penetrate the abdominal wall since this viscus occupies a relatively large space within the peritoneal cavity. Knife wounds will cause simple lacerations, while high-velocity missiles usually produce jagged holes that are surrounded by contused bowel that will not prove satisfactory for suture. On the other hand, blunt trauma does not often lead to rupture of the colon since its relative mobility and elasticity protect it.

Perforation of the colon may also occur from foreign bodies that are swallowed, or are introduced through the rectum. Usually, all such objects that pass through the ileocecal valve will go through the colon easily though, in the presence of disease such as diverticulosis, a sharp-pointed object may be caught and will penetrate the bowel. Chicken or fish bones, toothpicks and needles are the usual causes of such perforations. The sigmoid also may perforate from the accumulation of large fecaliths in this part of the bowel. Fecaliths are particularly likely to form when a large diagnostic barium meal has been followed immediately by operation, so that ileus and dehydration combine to produce this mass. A great variety of foreign bodies have been introduced into the rectum from below and then lost above the contracting sphincter. If they are long enough they may perforate the sigmoid. In our hospital such a perforation has been observed from a giant-sized carrot used ostensibly for anal dilation to relieve constipation.

Perforation of the sigmoid is always possible when an inept sigmoidoscopy is done. For this reason utmost care must be used in every case. Sigmoidoscopes over 25 cm. in length should be employed only by experts and in very co-operative patients, since an inadvertent sudden movement by the patient may be disastrous. Usually in these circumstances, the perforation can be recognized by the sudden observation of the small intestine through the sigmoidoscope. However, occasionally it will not be suspected until the patient later complains of

enema tubes and enemas themselves may produce perforation. It is doubtful that the normal colon could be perforated by an ordinary enema, but a bowel wall, weakened by inflammation or cancer, may tear apart.

Workers about compressed air nozzles have occasionally, either by accident or design, received a blast within the rectum. This is an extremely dangerous accident which is likely to blow out the colon. The region of the splenic flexure is most likely to be involved. A somewhat similar disruption of the colon may occur rarely when the intestinal gases are exploded by a spark during electrodesiccation of a polyp through the sigmoidoscope.

The symptoms of perforation of the colon are pain and tenderness appearing first at the site of injury and spreading rapidly to involve the entire peritoneal cavity.

Nausea and vomiting usually follow and then are superseded by the signs of vasomotor collapse. A shocklike syndrome is particularly likely to occur after perforation of the right colon has filled the abdomen with liquid feces and virulent peritonitis is established. Occasionally the passage of blood by rectum will indicate an injury to the colon.

Treatment will depend upon the cause and the location of the injury and the amount of bacterial contamination. In general, it is safe to suture fresh wounds of the colon which have not vitiated the blood supply of the segment. In the presence of well-developed peritonitis, intraperitoneal sutures are much less likely to hold and, when there has been additional trauma to the bowel beyond the laceration, or damage to the blood supply, the exteriorization procedures are safer.

The earlier the operation is carried out, the better is the chance of success. Every attempt should be made to operate on the patient within six hours of injury. Furthermore, wounds of the right colon are more dangerous than those of the left because of the rapid dissemination of liquid feces when the cecum is lacerated.

The standard operation for injuries of the colon—exteriorization of the damaged segment—involves a wide mobilization of the colon to observe all areas of injury and withdrawal of the injured portion of the colon from the peritoneal cavity as a colostomy segment. In certain instances, when the perforation is in the low sigmoid or rectum, where the damaged area cannot be exteriorized, the perforation must be closed by suture and a completely defunctioning colostomy opening made, preferably in the

transverse colon. The colostomy stoma is closed by resection and intraperitoneal anastomosis four to six weeks later.

VOLVULUS

Volvulus is an important cause of obstruction of the colon. The term should be restricted to those cases which show a rotation of the bowel about its mesenteric axis sufficient to produce obstruction. While it may occur in any mobile portion of the intestine, in the colon it by far is found most commonly in the sigmoid. The cecum is involved less frequently and the transverse colon rarely. Megacolon and a consequent history of constipation usually antedate an acute volvulus by many years.

The disease is much more common in persons of advanced age than in younger individuals, and in males than in females. There is a great variation in incidence in different countries, suggesting that congenital causes are important. For example, it is much more common in Russia than in America. In our hospital, it causes about 4 per cent of all acute obstructions of the colon.

Pathologic studies show that the volvulus may be either clockwise or counterclockwise. Such a twist rapidly produces a closed-loop obstruction that may be fatal shortly unless the situation is remedied. Increased tension within the loop leads to obliteration of the blood supply, gangrene, perforation, peritonitis and death. A rapid progression is most likely to occur in the cecum because of its thin wall that easily becomes avascular.

The symptoms are those of large bowel obstruction. The lower abdominal cramps are followed by obstipation and distention. In early cases, the distention is limited to the obstructed loop, though later it becomes generalized. Absence of peristalsis or tenderness is a serious sign indicating strangulation. An abdominal x-ray examination usually shows an enormous loop of colon filled with gas and fluid. Since the twisted loop may appear in an unusual position, a barium enema should always be employed to confirm the diagnosis and locate the volvulus anatomically. Thus, a twisted cecum is not infrequently palpable in the left upper quadrant and, without a barium enema, an unfortunate incision may be made for its correction. Characteristically, the barium enema will outline the lower end of the volvulus, showing a cone-shaped deformity which may resemble a bird's beak, at the point of obstruction.

The treatment of volvulus of the colon is

surgical. However, it must be recognized that spontaneous reduction of the volvulus may occur if the twisted loop can be deflated. When the sigmoid is involved and there is no evidence of strangulation of the blood supply, deflation often can be accomplished by the careful introduction of a rectal tube through a sigmoidoscope. Needless to say, such a maneuver must be done with great care. When the cecum is involved, resection and primary anastomosis may be carried out in good-risk patients. Resection is necessary if the blood supply is questionable. Otherwise an alternative procedure is detorsion, fixation of the cecum is then accomplished by means of cecostomy. When the sigmoid is involved and the patient in good condition, resection and anastomosis likewise are feasible, sometimes, simple detorsion, which will be followed by resection at a second stage, or detorsion plus an obstructive resection, will be wise. In all patients, unless the offending loop has been resected, there is a great tendency to recurrence. Careful attention to the bowels, with the avoidance of constipation or distention, is essential.

INFLAMMATORY DISEASES

The important inflammatory diseases of the colon include ulcerative colitis, bacillary dysentery, amebiasis, tuberculosis and actinomycosis. Diverticulitis, since it depends on the presence of diverticulosis, will be discussed as a separate entity. Recently an acute enterocolitis, usually due to the staphylococcus, has emerged as an important post-operative complication. It is particularly apt to follow resections of the colon for cancer. Lymphogranuloma primarily affects the rectum but also may involve the sigmoid colon.

Bacillary Dysentery. This disease is of minor importance to the surgeon. Occasionally, in the subacute or chronic form, it may be mistaken for chronic ulcerative colitis, since, on sigmoidoscopic examination, ulcers may be seen along the transverse ridges of the lower colon. Later, these ulcerations tend to coalesce and to encircle the bowel. Bacteriologic study of the organisms isolated from these ulcers should reveal one of the dysentery bacilli.

Amebiasis. Amebas are ingested as cysts, the walls of which are dissolved in the small bowel. Free, motile amebas then enter the mucosa of the large bowel. Initially, widespread ulcerations are produced, involving particularly the cecum, ascending colon and upper rectum. Superficial, ragged ulcers are

produced that penetrate below the upper layers of the submucosa. Motile amebas are recovered regularly from these fresh ulcerations and usually in warm stool preparation. The diagnosis of acute amebic dysentery can be made by this method, since the ulcers are nearly always observable through the sigmoidoscope at this stage of the disease.

Later in the course of the disease, chronic colitis is produced which may progress to the formation of large granulomas or amebomas, as they sometimes are called. Amebomas are often confused with cancer since the other signs of amebiasis may be absent. These granulomas have been encountered in all parts of the colon but are most common in the cecum and rectum.

Amebiasis of the colon is of surgical significance chiefly because it mimics other diseases. The differentiation of amebic colitis and ulcerative colitis is often different in the acute and chronic stages, while the granulomas are likely to be resected in the belief that they are cancer. Specific complications referable to the disease are perforation and hemorrhage. Perforation usually occurs in the cecum or in the appendix, which is involved in about 40 per cent of the subjects of amebic dysentery. The most important complication of amebiasis is liver abscess, it should be suspected in the presence of increased fever or marked leukocytosis.

Tuberculosis. Tuberculous enterocolitis is encountered rarely except in sanatoria since it is usually secondary to pulmonary tuberculosis. This secondary tuberculous enterocolitis was found by Rubin in two-thirds of a series of 569 patients who died of pulmonary tuberculosis. Primary ulcerative enterocolic tuberculosis is a very rare disease in the United States at this time because of milk pasteurization. Either of these lesions may lead to a granulomatous form known as hypertrophic intestinal tuberculosis. In this type of disease, a large inflammatory tumor is produced somewhere in the intestinal tract and is followed by the observation of a mass or by subacute intestinal obstruction. The cecum is the usual site of disease. Some of these cases actually are manifestations of regional enterocolitis. The disease is rare, but, when it occurs, surgical resection is required.

Regional Enterocolitis. Regional enteritis always involves the small intestine, but, in certain instances, a similar disease may occur that is confined to the terminal ileum and ascending colon. This lesion is more closely related to regional enteritis than it is to

ulcerative colitis. It tends to remain localized in this area and therefore the results following resection and anastomosis are good.

Chronic Ulcerative Colitis. This is a disease of unknown cause, manifested by chronic colitis with ulceration. While it follows a typical clinical course, the diagnosis is usually established by the elimination of other etiologic agents. Many causes of the disease have been suggested, such as specific bacteria, viruses, fungi, allergies, digestion of protective mucous membrane by the enzyme, lysozyme, and abnormal colon function due to disordered nerve reflexes.

Clinically, the disease usually starts abruptly, most commonly in the individual's third decade of life. Diarrhea, which usually is bloody, fever and loss of weight occur. Unless the first acute attack is fulminant, leading to surgery or death, the patient improves, but the disease tends to become chronic with repeated exacerbations.

The diagnosis is usually made by sigmoidoscopy, since in about 95 per cent of the subjects the disease begins in the upper rectum and spreads back to the cecum, often for a short distance in the small bowel. Occasionally the disease may start in the right colon. The barium enema will demonstrate saw-tooth serrations along the margin of the bowel in patients in the early phase of the disease, but, as the disease progresses, the colon becomes shortened and tubular, with loss of haustrations.

Sigmoidoscopic examination in an early stage shows an edematous, boggy mucous membrane which bleeds on wiping. Later, irregular superficial ulcerations appear. The ulcers deepen and may penetrate the bowel wall. Meanwhile, normal mucosa disappears. Attempts at regeneration lead to pseudopolyp formation. Cancer is likely to develop later in any portion of the involved colon.

Medical measures used for therapy include a bland diet, sedatives, antispasmodics, elimination of all known psychic problems and, in numerous cases, cortisone or ACTH. They are usually successful but will fail in at least a quarter of the patients. Surgery becomes necessary for those patients who cannot be controlled otherwise. The indications for surgery are numerous. In the first attack, debilitating diarrhea, high fever and toxemia may make surgery necessary within the first two weeks of symptoms. Fortunately, cortisone or ACTH therapy is most helpful here. More often these same symptoms are alleviated to some extent, but surgery is necessary in the chronic phase of the

Figure 72. Ileostomy. This type of ileostomy will defunction the entire colon. It is used particularly in the surgery of ulcerative colitis and multiple polyposis involving the entire colon and rectum. The ileum is divided between clamps and the stoma made in the right lower quadrant.

disease. Complications referable to the colon requiring surgery are subacute perforation, abscess or fistula formation, obstruction, persistent or severe hemorrhage and the development of pseudopolyps. Other complications that can be improved only by ileostomy and colectomy include infectious arthritis, uveitis and, occasionally, widespread cutaneous infections.

Surgical therapy includes ileostomy (Fig. 72). At the present time this is nearly always combined with subtotal colectomy or with total colectomy and proctectomy. Ileostomy alone usually will relieve symptoms, and the appearance of the colon as visualized through the sigmoidoscope will improve. However, despite this improvement, it is not wise to consider closure of the ileostomy stoma at a later date, since this nearly always leads to an exacerbation of the disease. Thus, in a series of 149 patients with ulcerative colitis treated surgically in the Massachusetts General Hospital, reported by McKittrick and Moore, closure was thought advisable in only five instances and was a success in only

one. Furthermore, many complications can follow ileostomy. They include stenosis of the stoma, prolapse of the distal ileum through the stoma, intestinal obstruction due to prolapse of the ileum about the terminal ileum, and fistula formation about the stoma. One of the most serious of these complications—the so-called ileostomy dysfunction—actually is a type of obstruction due to a stoma which is blocked by edema or granulation tissue. Suture of mucosa to skin has essentially eliminated this problem. These complications are most common within the first few months after the establishment of the ileostomy opening. When this period is over the patient can lead a relatively normal life, thanks to the development of bags that can be cemented to the skin.

Later in life, however, if the colon has not been removed, cancer of the colon is likely to develop. Statistical studies by Dennis and Karlson indicate that the chances of cancer are almost nil within the first ten years after ileostomy but increase regularly after that time, at the rate of about 1 per cent a year. It therefore seems wise, in the light of our present knowledge, to advise total removal of the colon and rectum after an ileostomy opening has been made.

Recently an increasing number of patients, particularly in older age groups, have appeared with segmental ulcerative colitis which is amenable to segmental colectomy. Whether or not this is the same disease as that observed in younger patients is not clear.

DIVERTICULOSIS AND DIVERTICULITIS

Diverticula of the colon are abnormal herniations of mucosa through the muscular coats of the bowel which produce small saclike projections. Inflammation of these diverticula sufficient to produce symptoms, or visible evidence of localized spasm of the colon on x-ray study or sigmoidoscopy, is known as diverticulitis.

The etiologic background of the disease is not known except for solitary cecal diverticula which are believed to be congenital in origin. Other diverticula appear near to blood vessels that run from the mesentery through the wall of the bowel. It is presumed that this intrinsic weakness of the bowel is followed by increased intracolonic pressure with the production of diverticula. The predilection of the disease for the sigmoid is accounted for by the fact that feces in this area are much firmer than elsewhere. The anatomic curvature of the sigmoid may

contribute. Furthermore, spasm in the sigmoid is common, especially during the expulsion of feces, while it is not observed in the cecum and ascending colon. At any rate, it is clear that diverticulosis is one of the degenerative diseases, appearing rather uncommonly in persons below the age of fifty years and becoming more common thereafter as age advances.

Autopsy studies have shown that about 7 per cent of all colons have diverticula. Careful barium enema examinations should show a much higher incidence since demonstration is more exact by this technique. In a check of 2000 consecutive persons in the Massachusetts General Hospital who had been administered barium enemas, essentially neither diverticulosis nor diverticulitis was found in persons below the age of thirty-five years. From that point onward the disease increased rapidly in frequency, so that diverticula could be demonstrated in two-thirds of the eighty-five-year-old patients and the individual diverticula increased in size with age. The incidence of diverticulitis also showed a steady rise.

Diverticulosis is rare in the rectum and in the cecum. According to Mailer's autopsy studies, it was confined to the sigmoid (Fig. 73) in 40 per cent of the subjects and scattered throughout the entire colon in 30 per cent. It is more common in the male than in the female.

In the Massachusetts General Hospital, of the patients requiring surgery for diverticulitis, 92 per cent had involvement of the sigmoid or lower descending colon, 3 per cent of the cecum, 3 per cent of the rectum and 2 per cent of the transverse colon.

It is often impossible to tell the exact time diverticulosis undergoes transition to diverticulitis. Certainly many, or all, patients having pure diverticulosis are entirely asymptomatic. The symptoms of diverticulitis are alteration of bowel habit, pain, tenderness and bleeding.

Alterations in bowel habit include constipation, diarrhea, gas and distention. They are difficult to evaluate in many instances. However, distinct episodes of diarrhea, particularly when they are accompanied by left lower quadrant pain and tenderness, are very suggestive of diverticulitis. Constipation is common and becomes more severe if inflammatory narrowing of the bowel occurs.

Pain is of two types. One consists of cramplike attacks that are relieved by the passage of gas or stool.

passage of gas or feces. The other consists of localized pain and tenderness due to actual inflammation about the diverticula. The latter, of course, may progress to varying degrees of peritonitis.

Bleeding is not an infrequent symptom. Theoretically it should not occur with diverticulosis per se. Probably it occurs in 15 to 20 per cent of all patients with diverticulitis. The source of the bleeding may be coincidental hemorrhoids, cancer, polyps, pseudopolyps, acute nonspecific ulcer occurring in an area of diverticulitis or the diverticulitis itself. Persistent daily bleeding is more characteristic of cancer.

The indications for surgery include perforation, obstruction, hemorrhage and persistent discomfort unrelieved by medical care.

Perforations vary greatly in significance. A perforation into the mesenteric fat may produce only a minimal amount of pain and tenderness. In other instances, a large inflammatory mass may be produced. If perforation occurs into the general peritoneal cavity, a localized abscess or general peritonitis will occur. The clinical signs will parallel these manifestations. Fever and leukocytosis of varying degrees are found. With free perforation, gas may be demonstrated below the diaphragm by x-ray examination. The pain from acute penetrating diverticulitis of the sigmoid may be felt chiefly in the right lower quadrant, so that acute diverticulitis may be confused with appendicitis.

One of the clinical features of diverticulitis is that of the progression of local perforations to form fistulae, which usually extend into the bladder, but the small intestine, other portions of the colon, vagina or skin all may be involved. Sigmoidovesical fistulae are much more common in the male than in the female because the uterus often forms a protecting barrier between the colon and bladder.

Though diverticulitis produces nearly 15 per cent of all the acute colonic obstructions observed in our hospital, it characteristically produces a chronic, slowly progressive obstruction, so that acute complete obstruction without any previous symptoms is not common. It is surprising to note how severe a degree of stenosis may be observed radiologically and the patient still have fairly adequate colonic function. Abdominal cramps, relieved by the passage of gas or feces, are early symptoms suggesting mild obstruction. They are followed later by

gradual distention and, in rare instances, by complete obstipation.

Bleeding is an indication for surgery in a few instances because it is so massive that control of blood loss is necessary. In other cases, continued bleeding and a questionable radiologic picture that could be either diverticulitis or cancer will make surgery wise.

The acute phases of diverticulitis usually can be treated medically with relief. If these acute episodes occur rarely after long intervals of freedom from discomfort, the patient may prefer to continue with this therapy. Attacks recurring in close succession, particularly if they occur while on adequate dietary regulation, make surgery necessary.

The differentiation of cancer and diverticulitis is often very difficult since the symptoms may be the same. Sigmoidoscopy may give no clue. The radiologist usually is able to distinguish them, though occasionally he may be wrong in his diagnosis or the diseases may coexist.

Schatzki has noted the important radiologic features of diverticulitis and cancer of the sigmoid. Diverticula are typically present with diverticulitis and absent with cancer. A long segment of the colon tends to be involved by diverticulitis and a short one by cancer. The mucosa in the involved segment is normal with diverticulitis and destroyed by cancer. The adjacent colon is spastic with diverticulitis and normal with cancer. The end of the defect is cone shaped with diverticulitis and shelflike with cancer. On

Figure 73. Diverticulosis of the sigmoid. Barium enema, postevacuation film. The diverticula are located entirely in the sigmoid. A single gallstone is seen.

repeated examinations, an enlarging lesion is very suggestive of cancer. Obviously, many cases are atypical, so that differentiation of the two diseases is impossible. Thus, in nearly 25 per cent of the patients operated upon for diverticulitis, cancer is suspected preoperatively, at the time of operation by the surgeon, and is only ruled out when the pathologist opens the specimen. This implies that the utmost vigilance must be used whenever a diagnosis of diverticulitis is made.

Experience has shown that several other groups of patients will eventually require surgery for diverticulitis. Those in whom the diagnosis is made before the age of fifty years have a particularly virulent form of the disease. Those who have severe persistent deformity of the sigmoid on radiologic examination have organic changes rather than spasm. Those who develop urinary symptoms in the presence of diverticulitis, particularly if they are males, must be suspected of developing a sigmoidovesical fistula. Resection of the involved segment of colon is advised for these groups of patients.

The medical therapy of diverticulitis consists of a low residue diet, daily doses of mineral oil or a demulcent such as Metamucil, antispasmodics and sedation. The more acute phase will require sharper restriction of the diet and antibiotics if there is evidence of perforation.

Surgical therapy has as its objective the wide excision of the involved section of the colon and re-establishment of intestinal continuity. This can be accomplished in one stage in many instances. Perforation or complete obstruction will make a colostomy desirable as a first-stage procedure, to be followed later by resection and anastomosis and, at a third stage, closure of the original colostomy opening. As an alternative procedure, in the presence of perforation or obstruction some surgeons prefer an obstructive resection.

Nearly three-quarters of all the patients will respond to medical therapy. Those treated surgically by a generous resection nearly always remain free of symptoms even though diverticula develop later in remaining portions of the colon.

BENIGN TUMORS

The benign tumors which arise in the colon or rectum are important because they often are precursors of malignant lesions and many produce symptoms which require relief. They are most easily classified by

their histologic appearance. They include the common adenomas and the rarer tumors such as lipomas, fibromas, angiomas, leiomyomas, carcinoids, endometriomas and pseudopolyps. These lesions nearly always protrude into the lumen of the bowel and therefore may be described as polyps. Polyp, by definition, is a nonspecific term insofar as the histologic pattern is concerned but commonly is used to designate an adenoma, since the adenomas are far more common than are all other types of benign tumors combined.

Adenomatous Polyps. Helwig found a 95 per cent incidence of polyps of the colon and rectum in 1460 autopsies and noted an increase in number with age. Long series of sigmoidoscopies on asymptomatic patients have shown a very similar incidence.

Wilson, Dale and Brines did sigmoidoscopic examinations on 20,847 patients, all of whom presumably were asymptomatic. They found the incidence of polyps to rise steadily with age. In males, it was 2.6 per cent in those below the age of forty, increasing to approximately 11 per cent at the age of seventy or over. In females, the curve is distinctly lower, rising from 1.7 per cent under age forty to less than 5 per cent at age seventy. Thus, Hauch, Bue and Smith found adenomas in 8.1 per cent of 1919 patients. Approximately two-thirds of all adenomatous polyps are found in the rectum. Most of the others are found in the sigmoid and the remainder are scattered throughout the colon.

Adenomatous polyps may be classified in several ways. Depending upon their number, they fall into three distinct classes. In the first, a single or a few polyps are located in one segment of the bowel. In the second (scattered polyposis), a few polyps are found in different segments of the colon and, in the third, multiple polyposis, the polyps are both numerous and widely disseminated (Fig. 74). Grossly, the individual polyp may be described as pedunculated or sessile, but this is of much less importance than the microscopic picture. Histologically, these lesions are either benign adenomatous polyps, benign polyps with malignant degeneration of a portion of the polyp or papillary adenomas.

The cause of polyposis is not known. A definite familial susceptibility has been demonstrated in persons having multiple polyposis and may well be present in others.

It is generally believed that adenomatous polyps eventually develop into clinical can-

cer. This transition has been observed rarely but was seen by Buie and Brust in a period of two to ten years in four patients who refused treatment. Other arguments favoring this conclusion are that the distribution of polyps and cancer is similar throughout the colon; that the incidence by age and sex is approximately the same for the two lesions; that polyps are found in about 25 per cent of all colons resected for cancer and usually in close proximity, and that frequently multiple lesions can be demonstrated in the colon which show all changes of transition from benign polyp to invasive cancer. Patients with multiple polyposis nearly always die of cancer before the age of forty years unless a colectomy has been done.

Recently, Spratt, Ackerman and Moyer have introduced evidence to indicate that benign polyps do not degenerate into cancer. This concept, however, should not influence the clinical surgeon who must realize that the only method of differentiation between benign polyp and polypoid cancer is by microscopic analysis of the resected tumor.

Polyps often are entirely asymptomatic. If symptoms occur they comprise bleeding, change in bowel habit, abdominal discomfort or the discharge of mucus by rectum. Bleeding is the most common symptom. While it usually consists of blood streaking on the surface or in the substance of the stool, it may occasionally be very profuse. Diarrhea is particularly common with multiple polyposis, but constipation also may occur. Intussusception of the polyp may lead to bleeding and cramps.

The diagnosis is made by sigmoidoscopy or barium enema. Sigmoidoscopy must always be done as the first step. Later a barium enema is given. Preferably this is followed by an air contrast enema. Demonstration of polyps by barium enema is often difficult and usually impossible until the polyp is over 1 cm in diameter. The bowel must be completely prepared or fecal lumps will be mistaken for polyps. If a defect is found that is consistent with a polyp, the barium enema must be repeated to confirm the diagnosis before surgery is undertaken.

Unless there are serious contraindications, polyps should be removed. By no other way than microscopic examination can they be differentiated from cancer. When the lesion is located in the colon, this generally means that a laparotomy is necessary, though some small polyps of the sigmoid can be removed safely through the sigmoidoscope.

At the time of laparotomy the surgeon

must find the polyp, determine whether it is benign or malignant, discover whether other polyps are present or not and then carry out the appropriate operation. In the individual patient this is often a difficult problem and it is not surprising that surgeons do not always agree on the most satisfactory procedure. Examination of the colon by the sigmoidoscope at the time of laparotomy through one or more colotomy incisions has been proved to be the best method to demonstrate small polyps.

From a practical point of view, it may be said that two operations are possible. In the first—colotomy and polypectomy—the colon is opened and the polyp removed locally. A frozen section is made whenever possible to confirm the diagnosis of benignancy. This operation should be avoided whenever the polyp is hard or has a broad base, since cancer is likely to be present.

The second operation which may be done is segmental resection of the colon. The author, among others, prefers this procedure as a routine on several bases. Cancer is relatively common in these polyps, as shown by a series of 102 colonic polyps in our hospital in which cancer was found in 24 per cent. Also, recurrence of supposedly benign polyps that have been removed locally is not rare. Judd and Carlisle followed 246 patients from the Mayo Clinic five years or more after transcolonic polypectomy had been done. They found definite clinical cancer of the colon had developed in fifteen of these. Local recurrence was the rule if there was

Figure 74. Diffuse polyposis of the colon. Resected specimen. The terminal ileum and colon, except for the terminal sigmoid, are shown. Polyps are present in all portions of the colon. The terminal ileum is in the lower portion of the outer circle.

any microscopic evidence of invasive cancer. In these patients, in contrast to those with lesions of the rectum which can be kept under observation with a sigmoidoscope, local recurrence cannot be detected until a very sizable tumor is present.

In a series of cases in the Massachusetts General Hospital, thirty-four patients had local excision of a malignant polyp of the colon or rectum and nine were later found to have metastases or to have died of cancer. Microscopic examination determines the prognosis, since all patients with recurrence had adenocarcinoma, grade II or III. Those with adenocarcinoma, grade I, did well after local resection.

Multiple Polyposis. In the typical patient with multiple polyposis, there are hundreds of polyps scattered throughout the colon and rectum. The most serious variant is "polyposis en nappe," when the whole colon is carpeted with polyps. They usually develop in childhood and may be associated with polyps of other portions of the gastrointestinal tract. Jeghers noted that these patients often have melanin spots on the lips. The disease is hereditary, is present in male and female and may be transmitted either as a dominant or recessive characteristic. Whenever the disease is found, other relatives of the patient ought to be examined.

Treatment depends upon the location of the polyps. If the rectal mucosa is completely covered with polyps, the entire colon and rectum will have to be sacrificed and an ileostomy done. If the rectum is comparatively normal, a subtotal colectomy can be done, and the ileum anastomosed to the upper rectum. Later, the rectal polyps will be destroyed by electrocoagulation. Needless to say, careful follow-up observation of the rectum must be made for many years.

Papillary Adenoma. This is a special type of polyp which tends to be large and soft, with elevated papillary folds. It tends to spread laterally and is prone to develop malignant degeneration. Microscopically, these tumors present a distinctive picture of large villi covered with proliferating epithelium.

While nearly 10 per cent of polyps are of this type, the great majority of them occur in the rectum. Occasionally, however, they may be found in any other portion of the colon. In these areas, even if the surgeon knows where they are located, it may be totally impossible to feel them through the wall of the bowel.

In the colon these lesions must be treated

by segmental resection including a wide portion of the mesentery.

Other Tumors. Lipomas may develop in the submucosa of the colon and, by enlarging within the lumen of the bowel, produce a large submucosal tumor. Often they initiate an intussusception. They are, with the exception of polyps, the most common benign tumors of the bowel. The preoperative diagnosis is often possible on the basis of a long history and an intussuscepting tumor. Occasionally, the radiologist can demonstrate the typical radiolucent lipoma.

Endometrial implants are often found on the sigmoid and cecum. In the sigmoid colon, endometriosis may produce a constricting deformity which produces symptoms of colonic obstruction. Since the disease practically never involves the mucosa, radiologic examination should suggest the diagnosis. While symptoms are most apt to occur during the menstrual life, postmenopausal obstruction may occur. Pseudopolyps are actually inflammatory granulomas and not true tumors. They occur particularly with ulcerative colitis and occasionally with other inflammatory lesions.

The other benign tumors are rare and are usually diagnosed only by microscopic diagnosis of the resected specimen. They include angiomas, fibromas, leiomyomas and carcinoids.

MALIGNANT TUMORS

Malignant tumors of the colon essentially are restricted to carcinoma. The various forms of malignant lymphomas are encountered rarely. Liposarcomas, fibrosarcomas, malignant carcinoids with metastases, malignant melanomas and angiosarcomas occur rarely, while metastatic tumors from other sites, such as the stomach or breast, may produce colonic obstruction. An indication of the relative frequency of these tumors may be shown by the fact that, during a period of eleven years, 1300 cases of cancer of the colon were observed in the Massachusetts General Hospital while only nine colonic lymphomas, the next most common tumor, were encountered in forty years. Since the diagnosis and treatment of all malignant tumors are essentially the same, regardless of type, carcinoma of the colon will now be considered as an entity.

Cancer of the Colon. This is one of the most common types of cancer. According to the United States Public Health Service statistics, over 26,000 deaths occurred from this disease in 1958 and if the rate of the

colon and rectum are grouped together this is the most common of the fatal cancers. The disease is slightly more common in females than in males in the colon, while in the rectum this frequency is reversed, according to Ottenheimer and Oughterson who conducted an exhaustive statistical study of cancer of these viscera in Connecticut.

The cause of cancer of the colon is unknown. It is particularly common, however, in colons involved by multiple polyposis or by ulcerative colitis. In the latter disease, it appears to originate from areas of mucosal scarring and abnormal regeneration rather than from the pseudopolyps which often occur with ulcerative colitis. If cancer is encountered before the fourth decade, it usually is associated with one of these diseases. As noted above, many cancers are believed to originate from adenomatous polyps. Swinton and Warren believe they have found sound microscopic evidence of this origin in about 20 per cent of all cancers of the large bowel.

Symptoms are quite variable, depending upon the primary location of the tumor. It is best to consider lesions of the right and left colon separately.

In the right colon, early symptoms are usually vague and consist of indefinite flatulence or distention that gradually progresses to true cramplike pains. The picture often mimics gallbladder disease so that careful exploration of the colon is essential whenever a gallbladder is removed. Secondary anemia is very common since these lesions usually present a large infected surface that is easily digested by the ileal contents. This anemia often is the first symptom, so that anemic patients, particularly when they have many reticulocytes in the smear, must be investigated for cancer of the right colon. This anemia also may be encountered with lesions of the transverse colon but is rare with cancer of the sigmoid. The anemia is often manifested by fatigue and loss of weight. The stools, while positive for occult blood, rarely show gross blood. At times the first indication of the cancer is a large palpable mass, perhaps first detected by the patient. A change in bowel habit is common and usually is manifested by diarrhea.

In the left colon, symptoms differ because of the solid nature of the feces and the relatively small diameter of the bowel. Slowly increasing constipation is most common, though there may be short episodes of diarrhea. Bleeding with bowel movements is

common, bright or dark blood being mixed with the feces.

Occasionally the first symptom of colonic cancer is complete acute intestinal obstruction. This is less common when the cancer is in the right colon but occurs in perhaps 10 per cent of patients having cancer of the left colon, being most common when the tumor is in the splenic or sigmoid flexures. Other less common symptoms are those of perforation or intussusception.

The diagnosis, suspected from the history, must be confirmed by sigmoidoscopy and barium enema. Sigmoidoscopy is important, not alone to observe cancers of the lower sigmoid, but also to visualize any polyps which might be present in the rectum. Benign polyps coexist with cancer of the colon in about 25 per cent of all the patients and, while they are most common near the malignant tumor, may be found anywhere throughout the colon.

The barium enema study is extremely important and must be made with great care (Fig. 75). Even then some cancers of the colon may be overlooked. Cancer of the cecum and ascending colon is notoriously difficult to demonstrate, but it is also possible to miss cancer of other portions of the colon. Hence, if the examiner suspects cancer of the colon strongly, an exploratory lapa-

Figure 75 Carcinoma of the colon. In this barium enema study the colon is filled with barium, and the filling defect is clearly visible, indicating the presence of a tumor.

Figure 76 Distribution of carcinoma of the colon. The relative percentage of carcinoma arising in various segments is shown. The arterial blood supply of the colon is inserted. SM = superior mesenteric, IM = inferior mesenteric, IC = ileocolic, RC = right colic, MC = middle colic, LC = left colic, S = sigmoidal, S.H = superior hemorrhoidal.

rotomy may be necessary, at any rate, very careful follow-up will be essential.

Cancer of the colon is most common in the sigmoid flexure, where about 50 per cent of all colonic cancers are found, and occurs in order of descending frequency in the ascending, descending and transverse colon (Fig. 76). The lesion is nearly always an adenocarcinoma, though squamous metaplasia rarely may produce an epidermoid carcinoma. Malignant carcinoids are found rarely. The adenocarcinomas may be subdivided into several grades and, in many cases, the tumors produce large amounts of mucoid material forming the colloid carcinomas.

Spread of this cancer occurs in several ways: by direct infiltration of the wall of the bowel, by intramural extension along the wall, by lymphatic or blood-borne metastases or by direct desquamation of living cancer cells within the lumen of the bowel (Fig. 77). These factors are all of importance and will be demonstrated in varying degrees, depending on the type of the tumor and the length of time it has existed. Direct infiltration through the bowel wall will produce peritoneal carcinomatosis or, in more favorable cases, direct infiltration into another viscus or the abdominal wall. Intramural extension along the wall of the bowel is frequent but, in the absence of lymphatic metastases, only rarely is found more than 2 cm. from the primary lesion. Lymphatic metastases occur in about a third of our re-

Figure 77 Methods of spread of cancer of the colon. The five ways by which cancer of the colon is disseminated are shown. Extension occurs into the blood stream, into the lymphatics, by perforation through the bowel wall, by intramural growth, and by the shedding and reimplantation of viable cells in the lumen of the colon.

sected specimens. Four sets of lymph node are involved—the epicolic, the pericolic, the intermediate and the deep nodes. They follow the arterial blood supply. Blood-borne metastases follow invasion of veins by cancer. Microscopic incidence of this invasion was present in over 40 per cent of all patients having cancer of the rectum investigated carefully by Madison, Dockerty and Waugh, so that it is not surprising that hepatic metastases are frequent and early. That operative manipulation may contribute to tumor embolization has been proved by Fisher and Turnbull.

Nitrogen mustard, administered at the time of operation, theoretically should reduce the danger due to manipulation of these metastases. Cole has contributed important experimental data in proof of this concept.

Direct desquamation of cancer cells can often be observed by cytologic studies of the rectal discharge following a colostomy proximal to the tumor, so that it is reasonable to suppose that this occurs regularly. This factor is not of much importance except to the surgeon, who, after resection of the tumor and primary anastomosis of the colon, may implant cells in the fresh suture line and later observe recurrence at this site.

An important characteristic of cancer of the colon is its tendency to multiplicity. Two separate primary tumors are encountered not infrequently when the patient is first admitted to the hospital. Also, the development of new colonic cancer in later years is many times more common than in the nor-

mal colon. In approximately 5 per cent of patients having colonic cancer, multiple primary cancers develop. One of our patients, who did not have multiple polyposis, finally had seven primary lesions.

This is one of the important reasons that Wangenstein and co-workers have urged subtotal colectomy as the therapy of choice for cancer of the colon, though most surgeons still elect less extensive operations for single tumors.

Cancer of the colon is amenable to surgical extirpation since it usually grows slowly and remains localized for a long time. Wide block dissection can be accomplished with removal of involved adjacent viscera and usually a permanent colostomy can be avoided. The operation selected will depend primarily upon the segment of colon involved, the presence or absence of such complications of cancer as obstruction or perforation and the condition of the patient.

Generally speaking, operations involving exteriorization of the involved segment of the bowel have been discarded. Preferably, a one-stage resection of the colon, with a wide section of the mesentery, is accompanied by a primary end-to-end anastomosis (Fig. 78).

To attain this result with safety, the bowel must be prepared carefully and no important degree of obstruction can be present. Mechanical cleansing by mild cathartics or ene-

mas is most important. In recent years, great significance has been attached to the reduction of the bacterial flora of the colon by various antibiotics. There is no question but that the bacterial count of the stool can be reduced significantly by many drugs, particularly by the nonabsorbable sulfa derivatives such as Sulfathalidine or Sulfasuxidine, and, even more dramatically, by many of the broad-spectrum antibiotics such as Terramycin or neomycin. Unfortunately, nearly total abolition of coliform bacilli not infrequently has led to a compensatory proliferation of virulent organisms not responsive to antibiotics. Thus, pseudomembranous enterocolitis due to the *Staphylococcus pyogenes* var. *aureus* has emerged as an extremely serious complication of antibiotic therapy. Since this complication is very uncommon after the use of Sulfathalidine or Sulfasuxidine, this method of preparation is preferred at the Massachusetts General Hospital. Neomycin also appears to be relatively safe, while Terramycin has been dangerous.

Assuming that no element of obstruction is present, and a one-stage operation is to be done, a wide segmental resection of the colon is carried out. Before manipulation of the tumor, clamps or ties are placed about the colon near the growth to retain viable tumor cells released by manipulation of the growth. Preferably, at least 10 cm. of normal colon should be resected on either side of the

TECHNIQUE OF OPEN END-TO-END ANASTOMOSIS

Figure 78 Resection and anastomosis for cancer of the colon. The section of colon and mesentery to be resected is shown in the stippled area. After resection an outer posterior layer of interrupted cotton sutures is placed, followed by an inner one of fine continuous catgut. An outer anterior row of interrupted cotton is followed, when possible, by careful closure of the mesenteric defect.

Figure 79 Obstructive resection of the colon. A Rankin clamp is applied, after which the tumor-bearing portion of the colon will be excised with the cautery. At a later date the colostomy stoma will be closed. A limited portion of colon and mesentery is obtained by this method.

tumor. Preliminary ligation of the tributary blood vessels will reduce the chances of tumor emboli. The mesentery, lymph nodes and tributary blood vessels are excised down to the superior mesenteric artery on the right side. On the left side, the terminal portion of the inferior mesenteric artery must be removed with carcinomas of the lower sigmoid, while some surgeons prefer to remove

the entire vessel whenever the carcinoma arises in the left colon.

Certain technical details are of importance in every intestinal anastomosis. The anastomosis must lie without any tension. There must be an adequate blood supply and, preferably, pulsating arteries should be demonstrated over the cut edge of the bowel. The stoma should be made in such fashion that there is an adequate lumen. Two layers of sutures are preferred to assure a tight closure—the outer of interrupted cotton or silk and the inner of continuous fine chrome catgut. Finally, the rent in the mesentery must be closed to avoid any chance of post-operative herniation of a loop of small bowel. The anastomosis preferably is made in an end-to-end fashion, though, in certain instances, the surgeon may feel that after resection of the right colon, the lumen of the terminal ileum is so small that he prefers side-to-side ileocolostomy. Postoperatively, the proximal intestine must be kept decompressed for several days until the patency of the anastomosis is established.

When the carcinoma has produced complete intestinal obstruction, a much more dangerous situation has been produced. In about half of the patients, the ileocecal valve is so competent that the distended colon cannot decompress itself by evacuation into the ileum. Hence the Levin type, or any of the long intestinal tubes, cannot be relied upon to relieve large bowel obstruction. Furthermore, the distended cecum ruptures

Figure 80 Cecostomy. A cecostomy decompresses the colon, but does not sidetrack the entire fecal stream. Here, by a modification of the Gibson technique, a large rubber tube, supported by a right-angle glass tube, has been sutured in the cecum.

Figure 81. Transverse colostomy A transverse colostomy can defunction all the colon distal to it. Two types are shown here. A, The colon has been completely divided and the ends brought out at the margins of the skin incision. B, In this loop colostomy a section of the transverse colon has been delivered and is held in place by a glass tube passed through the mesentery. The colon is opened along the dotted line as soon as the peritoneal cavity has sealed off.

at a comparatively low pressure, so it is essential that colonic obstruction be relieved by operation as soon as possible after the patient arrives in the hospital.

When the obstruction is in the right colon, primary right colectomy is the operation of choice, though a side-to-side ileocolostomy will relieve obstruction if the ileocecal valve is incompetent. When the obstruction is in the left colon, a one-stage resection and anastomosis is hazardous, particularly in the presence of distention, so that the obstruction must be relieved first, either by cecostomy or transverse colostomy (Figs. 80 and 81).

The operative results vary considerably in different reports, depending upon material observed and the attitude of the surgeon. In a series of patients studied by Allen, Donaldson and me, 323 persons with cancer of the colon were observed from 1943 to 1954. Although no hope of cure could be entertained in many because of distal metastases, 96.6 per cent had resections of the tumor. The operative mortality of patients who had resections with the hope of cure was 2.3 per cent. The results showed that considering all patients seen, 47 per cent were alive five years after operation. The most important feature was that 66 per cent of all patients

who had resections for cure were still alive five years later.

The Anal Canal and Rectum

By J. PEERMAN NESSELROD, M.D.

JERROLD PEERMAN NESSELROD, a North Dakotan, had his college and medical education at Northwestern University. With an excellent basic education in anatomy preceding his surgical training, he has devoted himself to proctology and the development of proctoscopic cinematography.

The all too common mismanagement of anorectal problems reflects a lack of understanding of the fundamental principles involved in this field of surgery. To appreciate fully the diagnostic pitfalls and the proper treatment of anorectal deformities, diseases and injuries, a review of anorectal anatomy and neurophysiology is helpful.

A common error on the part of both patient and physician is to consider all trouble pertaining to the outlet of the intestinal canal as "rectal trouble." Paradoxically, the neurophysiology of the terminal gut is such

that the rectum is frequently the site of serious disease which is asymptomatic early in its course and is therefore discovered late—often too late—unless a thorough examination is made. The neurophysiology of the anal canal is such that involvement of these tissues is promptly called to the patient's attention and, thus, to the attention of the physician. In fact, anal disease is much more common than rectal disease.

Anal canal (anus) is the terminal segment of the intestinal tract. It varies in length from 1.5 cm. (in the female) to 2.5 cm. (in the male).

male) to 3 cm. It is bordered proximally by the dentate margin and distally by the anal verge (Fig. 82).

Rectum is the terminal segment of the colon proper. Its length is about 15 cm. The rectum is bounded inferiorly by the dentate margin. Superiorly, it joins the sigmoid colon at approximately the level of the second or third piece of the sacrum. This juncture, by no means distinct, is called the rectosigmoid.

Anorectum is a term which has crept into recent surgical literature. It pertains, of course, to both anal canal and rectum. The practical value of this term is to emphasize the importance of the anal canal (anus), as well as of the rectum.

Developmental Anatomy. The tissues forming the anal canal are derived from the embryonic proctodeum and are thus ectodermal in origin. The rectum, developed from the hindgut, is entodermal in origin. The anal plate, which early occludes the anorectal outlet, disintegrates in the seventh week of fetal life. Partial or complete failure of any or all of these complex processes results in congenital deformities, such as partially imperforate anus (congenital anal stenosis), completely imperforate anus, abnormal location of the anus, arrested descent of the rectum, atresia of the rectum and communication of the rectum with the bladder, urethra, uterus, vagina or perineum.

Gross Anatomy. *Anal canal (anus).* The anal canal is lined by thin anal skin, not mucous membrane, and is surrounded by the external and internal sphincteric muscles

which hold the anal walls in apposition and thus occlude the canal during its normal state of rest. The fibers of the anal levator muscles pass between the external and internal sphincteric muscles to find attachment to the lateral anal walls (Fig. 82). The long axis of the anal canal extends antero-superiorly toward the umbilicus.

The serrate dentate margin (Fig. 82), forming the superior boundary of the anal canal, comprises the anal papillae and the intervening anal valves. Immediately external to, and slightly inferior to, the dentate margin are the anal crypts, eight to twelve in number. Anal skin invests the component parts of the dentate margin and partially lines the crypts. Vestigial anal glands communicate with the crypts via the anal ducts.

Support to the anal canal is provided by the sphincteric musculature, the anococcygeal body, the perineal body and the pelvic diaphragm (the anal levator and coccygeus muscles and their investing fasciae).

Rectum. The mucosal lining of the distended rectum (i.e., from one atmosphere of pressure) is smooth except for the three prominent reduplications of mucous membrane which form the rectal valves of Houston.

The lower (distal) half of the rectum is retroperitoneal. The upper (proximal) half of the rectum is invested by peritoneum on its anterior and lateral walls (Fig. 82). Although the entire posterior rectal wall follows closely the sacrococcygeal curve, the

Figure 82 Diagrammatic representation of rectum and anal canal (coronal section).

Figure 83 Diagrammatic representation of blood supply and venous drainage of anorectum

long axis of the retroperitoneal portion of the rectum lies at a right angle to the long axes of both the anal canal and the proximal portion of the rectum. These anatomic facts are of practical importance to the student in his appreciation of both digital and endoscopic study of the terminal gut.

The principal supports of the rectum are the pelvic diaphragm, the rectal stalks and the mesorectum.

Blood Supply. The single superior hemorrhoidal artery and the paired middle and inferior hemorrhoidal arteries provide the principal blood supply of the anorectum (Fig. 83). The superior hemorrhoidal artery is the terminal branch of the inferior mesenteric artery. The middle hemorrhoidal artery arises from the hypogastric artery and the inferior hemorrhoidal artery is internal pudendal in origin. Since the internal pudendal artery, too, is hypogastric in origin, the surgical significance of the ligation of both hypogastric arteries, in addition to ligation of the inferior mesenteric artery, in the present-day performance of combined abdominoperineal proctoidectomy can be readily appreciated.

Venous Drainage. The superior hemorrhoidal vein is provided by the inferior mesenteric vein.

and by paired middle and inferior hemorrhoidal veins (Fig. 83). The internal portion of the hemorrhoidal venous plexus lies submucosally immediately proximal to the dentate margin, while the external part lies subcutaneously immediately distal to the dentate margin. From this plexus the hemorrhoidal veins take origin. The single superior hemorrhoidal vein is tributary to the portal system via the inferior mesenteric and splenic veins. The paired middle and inferior hemorrhoidal veins are tributary to the hypogastric veins and thus to the caval system. This anatomic arrangement is another point of practical importance with reference to the spread of infection and of malignant disease.

Lymphatics. The collecting vessels arising from the anal and perianal lymphatic plexus of origin are among the afferent vessels of the inguinal lymph nodes. These constitute an inferior pedicle or "downward zone of spread" (Miles).

The submucosal lymphatic plexus of origin is poorly developed in the lower rectum but constitutes a rich network above the rectal columns. The rectal collecting vessels and nodes accompanying the superior hemorrhoidal-inferior mesenteric artery comprise the superior pedicle of lymphatic collectors and correspond to the "upward zone of spread" (Miles). This pedicle is the principal lymphatic drainage of the rectum.

The middle pedicle, or "lateral zone of spread" (Miles), accompanying the middle hemorrhoidal artery, is thought to be the least important of the three.

Nerve Supply. The integument lining the anal canal and investing the structures of the dentate margin, together with the perianal skin, receives a somatic sensory nerve supply from the primary posterior divisions of the sacral and coccygeal nerves and from the primary anterior divisions of the second, third and fourth sacral nerves by way of the inferior hemorrhoidal branches of the pudendal nerve.

A somatic motor supply is provided for the external anal sphincter muscle via the inferior hemorrhoidal nerves and for the anal levator muscles via branches from the sacral plexus. The fibers of these muscles are striated. The internal anal sphincter and the remainder of the musculature of the terminal gut, being composed of smooth muscle fibers, receive a visceral motor supply through the autonomic nervous system.

The mucous membrane of the rectum is believed to receive a visceral sensory supply by way of autonomic nerves.

Neurophysiology. The practical importance of the nervous physiology of the anorectum is twofold. Anal lesions promptly cause sufficient sensory disturbance, usually pain, to bring the patient to his physician without delay. Rectal lesions, on the contrary, do not cause symptoms early, resulting in late discovery, or failure in discovery, of serious rectal disease unless the lesion is adjacent to the dentate margin. Thus, the absence of the sensation of pain in rectal mucosa provides a treacherous pitfall in the discovery of precancerous lesions and of early, asymptomatic, cancerous lesions. This same absence of pain sensation allows the surgeon to remove tissue from a rectal lesion for microscopic study and to apply electro-surgical methods in the removal or destruction of polyps without anesthesia.

These facts are pertinent to the establishment of four important rules:

1. The principal indication for proctoscopy is a patient.
2. Every patient whose history provides the slightest indication of disease of the terminal gut is a candidate for proctoscopy.
3. No physical examination is complete without proctoscopy.
4. Every candidate for proctoscopy harbors a serious lesion until the contrary is proved.

Surgical Spaces. A surgical space is potential only, but can be established as a reality by abscess formation or by dissection. There are five such spaces about the anorectum. The two ischiorectal spaces lie beneath the pelvic diaphragm and are therefore infra-diaphragmatic. The two pelvirectal spaces and the single retrorectal space lie above the pelvic diaphragm and are thus supradiaphragmatic. The surgical anatomy and relationships of the anorectal surgical spaces are shown in Figure 84.

Relations. The relations of the rectum to its neighboring structures are of practical

importance, first, with regard to physical diagnosis and, second, concerning surgical procedures.

Anterior to the distal half of the rectum in the male lie the prostate, the seminal vesicles and ducts and the urinary bladder. On palpation through the anterior rectal wall, the examiner can readily feel the prostate. He can also palpate the seminal vesicles if they are distended.

Anteriorly in the female are the vagina, the uterus and, anterolaterally, uterine adnexa. The accessibility of the uterine cervix to palpation through the rectovaginal septum enables the physician more safely to follow the course of cervical effacement and dilatation during the first stage of labor.

Extrarectal masses in the cul-de-sac in either sex are accessible to palpation through the anterior rectal wall. Nodular masses in the cul-de-sac may be "drop" metastases from an abdominal malignant growth. This anatomic relationship is of further practical importance in that the anterior wall of the proximal half of the rectum, above the level of the peritoneal reflection, provides a proper site for drainage of an abscess in the cul-de-sac. In the female patient such an abscess can be drained vaginally through the posterior fornix.

The important structures lying lateral to the rectum are the potential pelvirectal space, the pelvic diaphragm, the sacrospinous and sacrotuberous ligaments, the ischial spine, the sacral plexus and the piriformis muscle.

An abscess in the pelvirectal space will thus encroach on the rectal lumen from the involved side.

Of the anatomic landmarks lying lateral to the rectum the ischial spine is the most prominent. It serves to guide the examiner's finger to the immediately adjacent region of the greater sciatic foramen where the sciatic plexus and the piriformis muscle lie.

Figure 83 Diagrammatic representation of blood supply and venous drainage of anorectum

long axis of the retroperitoneal portion of the rectum lies at a right angle to the long axes of both the anal canal and the proximal portion of the rectum. These anatomic facts are of practical importance to the student in his appreciation of both digital and endoscopic study of the terminal gut

The principal supports of the rectum are the pelvic diaphragm, the rectal stalks and the mesorectum

Blood Supply. The single superior hemorrhoidal artery and the paired middle and inferior hemorrhoidal arteries provide the principal blood supply of the anorectum (Fig. 83). The superior hemorrhoidal artery is the terminal branch of the inferior mesenteric artery. The middle hemorrhoidal artery arises from the hypogastric artery and the inferior hemorrhoidal artery is internal pudendal in origin. Since the internal pudendal artery, too, is hypogastric in origin, the surgical significance of the ligation of both hypogastric arteries, in addition to ligation of the inferior mesenteric artery, in the present-day performance of combined abdominoperineal proctosigmoidectomy can be readily appreciated

Venous Drainage. Venous drainage is provided by a single superior hemorrhoidal vein

and by paired middle and inferior hemorrhoidal veins (Fig. 83). The internal portion of the hemorrhoidal venous plexus lies submucosally immediately proximal to the dentate margin, while the external part lies subcutaneously immediately distal to the dentate margin. From this plexus the hemorrhoidal veins take origin. The single superior hemorrhoidal vein is tributary to the portal system via the inferior mesenteric and splenic veins. The paired middle and inferior hemorrhoidal veins are tributary to the hypogastric veins and thus to the caval system. This anatomic arrangement is another point of practical importance with reference to the spread of infection and of malignant disease.

Lymphatics. The collecting vessels arising from the anal and perianal lymphatic plexus of origin are among the afferent vessels of the inguinal lymph nodes. These constitute an inferior pedicle or "downward zone of spread" (Miles).

The submucosal lymphatic plexus of origin is poorly developed in the lower rectum but constitutes a rich network above the rectal columns. The rectal collecting vessels and nodes accompanying the superior hemorrhoidal-inferior mesenteric artery comprise the superior pedicle of lymphatic collector and correspond to the "upward zone of spread" (Miles). This pedicle is the principal lymphatic drainage of the rectum

The middle pedicle, or "lateral zone of spread" (Miles), accompanying the middle hemorrhoidal artery, is thought to be the least important of the three.

Nerve Supply. The integument lining the anal canal and investing the structures of the dentate margin, together with the perianal skin, receives a somatic sensory nerve supply from the primary posterior divisions of the sacral and coccygeal nerves and from the primary anterior divisions of the second, third and fourth sacral nerves by way of the inferior hemorrhoidal branches of the pudendal nerve

A somatic motor supply is provided for the external anal sphincter muscle via the inferior hemorrhoidal nerves and for the anal levator muscles via branches from the sacral plexus. The fibers of these muscles are striated. The internal anal sphincter and the remainder of the musculature of the terminal gut, being composed of smooth muscle fibers, receive a visceral motor supply through the autonomic nervous system.

The mucous membrane of the rectum is believed to receive a visceral sensory supply by way of autonomic nerves.

mon to all the ordinary forms of anorectal inflammatory disease. *Stage III*, the final stage, will be discussed separately under each of the entities presented. Thus, each of the common disorders which have been listed is in reality a manifestation of anal infection. It is a common occurrence for patients to present any combination of these disorders as the result of anal infection.

HEMORRHOIDAL DISEASE

Hemorrhoidal disease pertains to any and all manifestations of hemorrhoids. Hemorrhoids, in turn, are vascular tumors made up of infected varices involving a part or all of the hemorrhoidal venous plexus (Fig. 86 A and B).

Mentioned frequently as causes of hemorrhoids are such factors as heredity, occupation, erect posture of man, lack of valves in the veins of man, portal obstruction, straining at stool, pregnancy and parturition. These factors, whatever their importance may be, serve only as contributing causes of hemorrhoids.

The principal etiologic agent in hemorrhoidal disease is anal infection.

The third stage of anal infection follows upon invasion of perianal and perirectal tissues by infectious material from the bowel. The normally thin-walled hemorrhoidal

venous plexuses are thus subjected to phlebitis, endophlebitis and further thinning of their walls, with resultant dilatation in varying degrees.

Hemorrhoidal disease may vary from an asymptomatic, chronic, inflammatory reaction, seen only on microscopic study of the tissues, to an acute, disabling episode characterized by severe pain, edema of anal tissues, multiple thromboses, gangrene, sloughing and ulceration, easily recognized clinically.

Pain is a prominent symptom of an external thrombosed hemorrhoid, as one might expect in view of the somatic sensory nerve supply of anal tissues, and is directly proportional to the amount of tension within the tissues. The "sore lump" of which the patient complains is due mostly to the clotted blood beneath the anal skin.

Bleeding occurs from a thrombosed external hemorrhoid only when the overlying skin has undergone erosion with resultant partial or complete extrusion of the clotted blood.

The symptoms suggestive, but by no means pathognomonic, of internal hemorrhoids are bleeding and protrusion. The patient may observe fresh blood on the toilet tissue, in the water in the toilet bowl or on his clothing. This, however, is of academic

Figure 86. Hemorrhoids. A, Coronal section showing both surface view and section of hemorrhoidal tissue. B, Hemorrhoids as seen at beginning of hemorrhoidectomy. C, Hemorrhoidectomy complete, ligature-excision technique.

The sacrum and coccyx lie posterior to the rectum. Between the sacrum and rectum is a potential space known as either the retrorectal space or the presacral space (Fig 84 B and C). Any mass in this space, inflammatory or neoplastic, if it be of sufficient size, will tend to obliterate the hollow of the sacrum and will encroach on the rectal lumen from behind.

The examiner can easily palpate and manipulate the coccyx by means of the examining index finger and the thumb. He can then sweep the index finger laterally and anteriorly to follow the sacrospinous ligament to the ischial spine and the sacrotuberous ligament to the ischial tuberosity. The findings may be of significance pertaining to coccygodynia and/or to otherwise unexplained pain which the patient thinks is "rectal" in origin.

ETIOLOGY AND PATHOGENESIS OF ANORECTAL INFLAMMATORY DISEASE

The principal underlying cause of the common anorectal inflammatory diseases,

such as hemorrhoids, anal fissure, anal abscess, anal fistula and anal stenosis which is spontaneous in origin, is anal infection. Anal infection pertains to the orderly sequence of events occurring in the development of these entities. Anal crypts, anal ducts, anal glands and adjacent blood vessels and lymphatics are the anatomic structures involved in this process.

Anal infection can be divided into stages (Fig 85)

In *stage I*, infectious material from the bowel content invades one or more anal crypts and the tiny vestigial anal ducts and glands attached thereto. Thus, Nature provides portals of entry into the perianal and perirectal tissues. Neither cryptitis nor trauma plays an essential role.

In *stage II*, infection is carried into the perianal and perirectal tissues indirectly by way of the lymphatics or directly through breaks in the continuity of the gland-duct structure, resulting possibly from overdistention.

Stages I and II of anal infection are com-

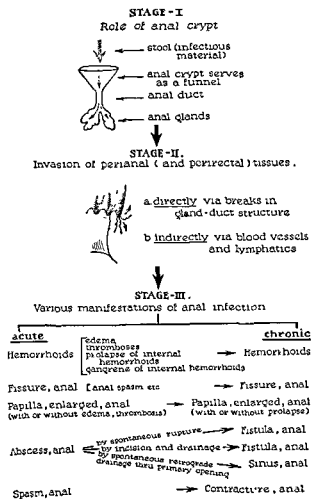

Figure 85 Diagrammatic representation of anal infection (Nesselrod, J. P., C.)

ment of hemorrhoids is threefold: the destruction of all external hemorrhoidal tissue, all internal hemorrhoidal tissue and all anal crypts, in view of the etiologic importance of anal infection.

There are three indications for adequate surgical treatment of hemorrhoidal disease: repeated attacks of "painful hemorrhoids," bleeding which may be responsible for hypochromic anemia, and annoying prolapse of internal hemorrhoids. Any one of these alone is a sufficient reason for surgical treatment.

The great majority of hemorrhoidal problems requiring surgical management are amenable to a ligature-excision type of hemorrhoidectomy (Fig. 86 C) which, in the hands of the experienced surgeon, is a remarkably flexible procedure. For the patient whose hemorrhoidal deformities involve the entire circumference of the anorectal outlet, an amputative-plastic procedure is indicated.

ANAL FISSURE

Although an anal fissure appears to be a crack in the anal skin, it is in reality an ulcer involving the entire thickness of the skin of the anal wall, usually the posterior anal wall, and lying in the long axis of the anal canal (Fig. 87 A).

The chief etiologic agent in anal fissure is anal infection, the first two stages of which have been described. Infectious material having gained entrance to anal tissues, infection can localize superficially in the subcutaneous tissues, inviting dissolution of the overlying anal skin (stage III of anal infection). The resulting defect in the anal skin is an anal ulcer. Failure of the ulcer to heal spontaneously or to respond to palliative treatment is due to the continuous mechanism of anal infection.

The characteristic symptom of anal fissure is cyclic pain of varying degrees of severity, initiated by defecation and lasting from several minutes to several hours. The pain is due to spasm of the anal sphincteric musculature and endures until the muscle is completely fatigued. Since muscle fatigue is accompanied by a subsidence of anal spasm, the patient gains welcome relief from his pain until the next occurrence of defecation.

Additional symptoms are slight bleeding at stool and a gradual trend toward constipation as a result of fear of painful defecation. In some instances of prolonged suffering from anal fissure, there may be abdominal discomfort, headache, irritability and nervousness.

An anal fissure may become sufficiently quiescent to cause little or no discomfort, giving rise to the erroneous conception of spontaneous healing.

The diagnosis is based upon the almost pathognomonic history of cyclic anal pain related to defecation and upon demonstration of the lesion (Fig. 87 A).

Gentleness in the handling of anal tissues in the presence of an acutely painful lesion is mandatory. Careful separation of the margins of the anus will disclose at least the distal part of the lesion. Exposure of the entire fissure is often difficult because of the accompanying anal spasm.

When the outlet is relaxed as the result of regional anesthesia, the margins of the fissure can be retracted easily, revealing the presence of a definite ulcer. Figure 87 A calls attention to an enlarged anal papilla proximal to the fissure. Immediately beyond the distal border of the fissure there may be a piling up of skin-covered tissue beneath which is frequently found a shallow pocket. This structure constitutes a sentinel tag, so-called because it seems to stand guard, as it were, at the distal border of the lesion.

Differential diagnosis necessitates consideration of a simple anal abrasion, specific venereal lesions such as chancre and chancreoid, a tuberculous ulcer, the ulcer of agran-

Figure 87 Anal fissure. A, Posterior anal fissure. B, Anal fissure excised. C, Multiple cryptotomy completed.

interest, because a serious lesion must always be considered the source of the blood until the contrary is proved. The loss of blood from internal hemorrhoids at any one time is of little significance compared with the summation of such losses of blood over a period of time, leading to hypochromic anemia.

Protrusion or prolapse of internal hemorrhoids occurs initially at defecation and recedes spontaneously. In time, the prolapse may occur with other forms of abdominal straining, such as coughing and lifting. Digital replacement of the prolapsed hemorrhoids becomes necessary. Ultimately, barring corrective treatment, the internal hemorrhoidal tissue remains prolapsed constantly, resulting in a discharge of blood and mucus which is irritating to the anal skin and which stains the clothing.

Diagnosis in any anorectal problem depends on careful and meticulous performance of inspection, digital palpation and proctoscopy. In the presence of an exquisitely painful anal lesion, proctoscopy is deferred until suitable anesthesia is provided, usually at the time of surgical intervention.

A thrombosed external hemorrhoid is found at the anal margin as a tender, bluish-colored swelling. The overlying skin is tense.

Differential diagnosis of external hemorrhoids requires consideration of anal epithelioma, condyloma latum, condyloma acuminatum and sentinel tag. The slightest doubt calls for biopsy.

Internal hemorrhoids are not visible on external inspection unless they protrude or unless the anal margins can be easily retracted. They are not palpable except when induration is present as the result of a recent inflammatory process. Internal hemorrhoids can be visualized readily by means of an anoscope or a proctoscope and are seen to be covered by a velvety rectal mucosa. Hemorrhoidal tissue, both external and internal, is commonly arranged in three groups: one on the left, one on the right posterior and one on the right anterior (Fig. 86 B). There may, however, be such extensive involvement of the hemorrhoidal plexus that hemorrhoidal tissue is arranged around the entire circumference of the anorectal outlet.

Acute, disabling, hemorrhoidal disease affects all parts of the hemorrhoidal plexus. A "collar" of edematous anal tissue containing multiple thromboses surrounds the anal outlet. The involvement of anal tissues is responsible for the disabling pain. In the center of the ring of external hemorrhoids are seen three masses of prolapsed internal

hemorrhoids. The internal hemorrhoidal tissue is edematous and may present discoloration, ulceration and gangrene in varying degrees and combinations. The term "strangulated hemorrhoids," often applied here, may lead to the belief that the strangulation is due to spasm of the sphincteric musculature. Actually, the examining finger can be inserted easily into the patient's anal canal, showing the absence of anal spasm. The strangulation is due to blockage of the internal hemorrhoidal varices by numerous thromboses.

Internal hemorrhoids should be differentiated from enlarged anal papillae, sessile and pediculate polyps and carcinoma. Anal papillae are invested by skin rather than by rectal mucosa, can be shown to arise from the dentate margin and are sensitive to pain stimuli. The microscopic study provides the final word with regard to neoplasm.

Protruding internal hemorrhoids require differentiation from an enlarged anal papilla with prolapse, a pediculate polyp with prolapse and rectal prolapse, either partial or complete.

The simplest management of a thrombosed external hemorrhoid seen within twenty-four or forty-eight hours is incision of the overlying anal skin, permitting extrusion of the clotted blood. Relief from pain is usually prompt because of the release of tension within the sensitive anal tissues. Such incision, however, is commonly inadequate, favoring the formation and retention of another clot.

Excision of the thrombosed hemorrhoid, employing infiltration of procaine to produce local anesthesia, is a more satisfactory method. It entails, of course, postoperative care.

In the instance of an acute, disabling attack of hemorrhoidal disease, conservative management, i.e., bed rest, ice packs and anodynes, is preferred. The risk of surgical intervention, when the tissues are edematous and are host to numerous, small, infected thrombi is great, chemotherapeutic agents and antibiotics notwithstanding.

Since sclerotherapy is applicable only to internal hemorrhoidal tissue, it cannot be considered a curative measure. Too, this method entails some risk. For these reasons the use of injection treatment should be limited to the patient whose problem is persistent bleeding from internal hemorrhoids and for whom adequate surgical treatment is contraindicated.

The objective in adequate surgical treat-

Throbbing pain and the classical signs of acute inflammation render the diagnosis of a superficial abscess rather easy.

The discovery of a deep (supradiaphragmatic) abscess depends upon a careful digital examination of the patient's rectum. A "doughy" swelling is found encroaching on the rectal lumen. The swelling is posterior in the instance of a retrorectal abscess and lateral in the instance of a pelvirectal abscess.

Any draining sinus lying in anal, para-anal or perineal skin must be considered to be a secondary opening of an anal fistula until proved otherwise. The opening may be bordered by granulation tissue and the surrounding skin is discolored. The opening may be found in scar tissue. Too, it may appear to be healed. Multiple openings are not uncommon.

Careful bidigital examination reveals a firm, subcutaneous "cord" leading from the sinus toward the anal wall. In reality, the cord leads from its primary source in the dentate margin to the opening in the skin. The cord of tissue is the fistulous tract or tube (Fig. 88 H). The exact origin in the dentate margin can be palpated if there is sufficient scarring. The digital examination may reveal also a submucosal cord arising at the level of the dentate margin and ending in a puckered mucosal scar. This process represents the internal limb of an anal fistula (Fig. 88 D).

Direct visualization of the dentate margin may disclose pus oozing from the involved crypt or sufficient deformity from scarring to identify the guilty crypt.

The use of probes in exploring the fistulous tract should be postponed until the time of surgical treatment.

A superficial abscess arising posterior to the anus must be differentiated from an acutely inflamed pilonidal cyst. The presence of one or more pilonidal openings may facilitate the diagnosis.

Draining sinuses which are pilonidal in origin have been found lateral to and anterior to the anus.

Perineal sinuses require consideration of disease and/or deformity of the genitourinary tract.

Multiple draining sinuses, especially when no anal origin is found, suggest the possibility of hidradenitis suppurativa involving the perianal apocrine glands.

Osteomyelitis of the pelvic bones may occasionally explain a draining sinus in the anal or para-anal tissues.

Either a true sinus or a fistula can result from a penetrating injury. The history, of course, is helpful in such instances.

Sacrococcygeal sinuses originating in presacral tumors and cysts are rare but must be considered.

An abscess requires drainage. The choice of a point for incision is important. If fluctuation is present the incision should be made at that point, but, in addition, it should be carried as near the anal verge as possible, without damage to sphincteric muscle, in order to shorten the resulting fistulous tract. Overhanging skin should be excised to provide adequate drainage.

In the case of a pelvirectal abscess, with or without involvement of the ischioirectal

Figure 88. Diagrammatic representation of pathogenesis of anal fistula. A, B, C and D pertain to a deep or supradiaphragmatic abscess and its resulting fistula. E, F, G and H pertain to a superficial or infra-diaphragmatic abscess and its resulting fistula. 1, Primary opening; 2, secondary opening.

ulocytic angina, ectropion and anal epithelioma.

Some relief can be had by means of such palliative measures as hot packs, sitz baths, anal hygiene and anesthetic ointments. Cure, however, depends on adequate surgical treatment and proper after-care. The surgical procedure comprises wide excision of the anal ulcer, including the underlying anal crypts, the enlarged anal papilla and the sentinel tag (Fig. 87 B).

The anal crypts in the remaining quadrants should be destroyed by means of extirpation (multiple cryptotomy) as a prophylactic measure (Fig. 87 C). Adequate surgical treatment is aimed not only at destruction of the anal fissure but also at avoidance of further anal infection.

ANAL ABSCESS AND ANAL FISTULA

Anal abscess and anal fistula are not separate entities. The former is a stage in the development of the latter. Thus, there is ample logic in Bue's presentation of these subjects under the same heading.

Anal fistula is a tube, inflammatory in origin, having its primary opening in an anal crypt. The secondary opening, or openings, may lie in anal, para-anal or perineal skin or in rectal mucous membrane (Fig. 88 H and D).

Anal sinus is a tube, inflammatory in origin, having its primary opening in an anal crypt and ending blindly in para-anal or pararectal tissue. Obviously, a sinus has no secondary opening.

Proper understanding of the accepted definitions of "fistula" and "sinus" should obviate further usage of such misleading terms as "blind internal fistula," "blind external fistula" and "incomplete fistula."

The chief cause of anal abscess and of the resultant anal fistula is anal infection, the earlier stages of which have been described. Thus, infectious material gains entrance to para-anal and pararectal tissues (Fig. 88 E and A). Although the anal ducts and glands lie superficially in anal subcutaneous tissue, they are occasionally sufficiently complex in structural arrangement to extend into the superficial fasciculi of the sphincteric musculature. Also, on occasion, they are seen to communicate with a crypt of Lieberkuhn immediately proximal to the mucocutaneous juncture. Hence, infection can localize in the tissues of the ischioanal fossa on one or both sides (infradiaphragmatic spaces) and, less commonly, within the rectal wall or in

the tissues of any or all of the potential pararectal spaces above the pelvic diaphragm (supradiaphragmatic spaces).

Such contributing factors as anatomic variations, virulence of the infecting organisms and resistance of the tissues of the host no doubt play a role in determining the clinical course and manifestations of the inflammatory process.

The acute phase of stage III of anal infection pertains here to abscess formation (Fig. 88 B and F). This phase soon passes into a chronic phase by one of three methods: spontaneous rupture of the abscess, incision for drainage of the abscess or spontaneous retrograde drainage of the abscess through its crypt of origin (Figs. 85 and 88 C and G). Either of the first two methods results in the establishment of an anal fistula (Fig. 88 D and H). The third method determines an anal sinus.

The abscess can involve any or all of the anorectal surgical spaces. Likewise the resultant fistulous process can have one or several limbs and one or several secondary openings. An internal limb has its secondary opening, or openings, in rectal mucosa (Fig. 88 D). The secondary opening, or openings, of an external limb lie in skin (Fig. 88 H).

Throbbing pain is the outstanding complaint when the abscess involves anal, para-anal or perineal tissues, since these tissues have a somatic sensory nerve supply. Such an abscess can involve a part or all of the ischioanal fossa, and is considered to be superficial because it is below, or inferior to, the pelvic diaphragm.

In the instance of a deep abscess involving a supradiaphragmatic space or of a submucosal abscess, pain is entirely absent early in the course of the trouble or is present only as a vague discomfort in the region of the rectum. Pain is not prominent until the process involves infradiaphragmatic tissues possessing a somatic sensory nerve supply.

The patient harboring a deep abscess is acutely ill. He presents chills, fever and a generalized malaise. Until he develops localized pain "in the rectum," the diagnosis is likely to remain undetermined or in error.

The chief complaint of the patient who harbors an anal fistula is periodic, spontaneous drainage by way of the secondary opening, with prompt relief of any discomfort which exists immediately prior to the drainage. This safety-valve mechanism often diverts a recurrence of the initial acute abscess.

until the little finger and finally the index finger can be passed.

The treatment of acquired contracture is preventive whenever possible. In routine postoperative care and in the care of injuries to anal tissues, the surgeon must learn to be constantly aware of the probability of contracture and must therefore make every effort to prevent such a complication. This includes separation of wound margins, digital dilation, irrigation of wounds and sitz baths, daily during the first week and at frequent intervals thereafter until healing is complete and satisfactory.

The corrective treatment of acquired contracture is surgical. Anal skin and subcutaneous scar tissue are incised radially at one or more points until ample room is provided in the anal canal. All anal crypts present are destroyed by means of exteriorization (cryptotomy) (Fig. 87 C). Thus, circumferentially arranged scar tissue is broken up by multiple radial incisions. The correction established here surgically must be maintained during healing by means of meticulous postoperative care.

BENIGN RECTAL STRICTURE

Benign strictures of the rectum may be either congenital or acquired; the latter, in turn, may be extrinsic, intramural or intrinsic in origin. Any extrarectal process, whether neoplastic or inflammatory, can encroach on the rectum with resultant narrowing of its lumen. In these instances, however, the rectal mucosa is usually intact, being involved only secondarily when there is malignant invasion of the rectal wall. Benign strictures which are intrinsic in origin may be the result of inflammatory disease, of trauma, of surgical procedures or of radiation therapy.

In the light of recently acquired knowledge, the most common cause of inflammatory rectal stricture is the virus of venereal lymphogranuloma (lymphogranuloma venereum). As the name implies, this entity is venereal in origin. Since the lymphatic drainage of the external genitalia is inguinal in either sex, a primary lesion of the external genitals in the male or the female is followed shortly by inguinal adenitis. In the female, however, the primary lesion is likely to be established in the vagina or on the cervix. As a result the virus can invade the perirectal and rectal lymphatics either by way of the plexus of the rectovaginal septum or through the uterosacral ligaments (rectal . In the male it is possible that the

infection may travel along the urethra into the lymphatics of the prostate and thence to the rectal absorbents by way of the rectal stalks. In either sex, infection may spread cephalad from an anal lesion, through lymphatic vessels which connect the anal absorbent plexus with that of the rectum. Lymphatic stasis in the presence of infection favors the growth of fibroblasts. The fibrous tissue thus formed undergoes contraction. The resultant inflammatory stricture occurs usually in the lower half of the rectum. The Frei test and a complement-fixation test are established diagnostic procedures.

Surgical procedures are often necessary, but the results are disappointing. The newer treatment of venereal lymphogranuloma includes such antibiotics as Aureomycin and chloramphenicol.

However, drug therapy has thus far proved useless once deforming stricture has occurred. For advanced rectal stricture the best plan appears to be to establish a permanent colostomy and then, if necessary, to remove the rectum by means of a combined abdominoperineal operation.

RECTAL PROLAPSE

The terms prolapsus and procidentia—meaning a falling down—are synonymous.

Buie's classification of rectal prolapse is both simple and logical. He divides the types of prolapse into those which are visible and that which is concealed. The visible prolapse may be partial, consisting only of rectal mucosa (Fig. 90 A), or complete, involving all the layers of the rectal wall. In the first degree of complete rectal prolapse the wall of the anal canal is everted too, so that there is no groove or sulcus surrounding the protruding mass of tissue (Fig. 90 B). In complete prolapse of the second degree the anal structures retain their normal positions, accordingly there exists a sulcus entirely surrounding the prolapsed gut (Fig. 90 C). Concealed rectal prolapse (complete prolapse of the third degree) is an intussusception of the upper portion of the rectum and rectosigmoid into the lower portion of the rectum (Fig. 90 D).

The chief underlying factor in the etiologic background of rectal prolapse is an alteration or defect in the supporting structures of the anorectum. The exciting causes are mechanical strain, disease and injury.

Partial prolapse must be differentiated from hemorrhoidal prolapse; in many instances the two conditions are associated.

Figure 89 Anal fistula A, Probe lying in fistulous tract B, Fistulotomy completed, deep half of fistulous tract lying in base of wound

fossa, drainage should be established through the ischio-rectal fossa and the pelvic diaphragm on the involved side rather than through the rectal wall. In the instance of a retro-rectal abscess, drainage should be established on either side of the anococcygeal ligament and as near the anus as possible. Fistulotomy should follow in four to seven days.

The treatment of anal fistula is fistulotomy, which entails laying open the entire tract from its primary source to its secondary opening and excision of overhanging margins (Fig. 89). An essential requirement is adequate relaxation of the anal outlet, best provided by means of sacral anesthesia.

The preference for fistulotomy, rather than for fistulectomy, is based upon the following considerations:

1. Fistulotomy follows logically upon the conception of the pathogenesis of anal fistula as has been presented. The same can be said of fistulectomy, but.

2. Fistulotomy is a much less extensive surgical procedure than is fistulectomy and yet is adequate. In the performance of fistulotomy, the tissues deep to the fistulous tract are not disturbed.

3. Fistulotomy allows conservation of tissue which is useful in the healing process. The membranous lining of the remaining deep half of the fistulous tract quickly ac-

quires a covering of granulation tissue. Scarring following this procedure is much less than that following fistulectomy.

4. Fistulotomy necessitates the sectioning of only those fibers of sphincteric musculature which are superficial to the fistulous tract.

Here, perhaps more than in any other problem of anorectal surgery, meticulous postoperative care is mandatory.

ANAL CONTRACTURE (STENOSIS, STRICTURE)

The terms anal contracture, anal stenosis and anal stricture pertain to narrowing of the anal outlet (anus).

Anal narrowing can be congenital in origin or acquired.

Congenital anal contracture or stenosis results from partial failure of disintegration of the anal plate in the seventh week of fetal life.

Acquired contracture can occur as a manifestation of anal infection, either alone or in conjunction with other clinical forms of anal infection such as hemorrhoids, anal fissure or anal fistula. It can develop as a result of a penetrating injury and can occur as a complication following anorectal surgery.

The mechanism in acquired contracture involves the well-known tendency of scar tissue to contract. When scar tissue is arranged circumferentially rather than radially about the anus, cicatricial contracture will cause narrowing of the anal outlet.

The chief complaint is difficulty, in varying degree, in passing stool. Pain and bleeding are common, especially if the anal skin is fissured.

In the infant an attempt at careful digital exploration, using the little finger, will usually determine the diagnosis. It may be impossible at first to pass the little finger, in which instance the careful use of a small Hegar dilator will aid in establishing the diagnosis and will serve to initiate therapy.

In the adult, too, digital examination may be difficult, depending upon the degree of narrowing. The small-caliber endoscope is especially useful when digital exploration is unsatisfactory.

Examination with the patient under regional anesthesia is indicated when the anal outlet is rigidly scarred and markedly narrowed. Surgical correction should be undertaken at the same time.

The treatment of congenital anal stenosis in the infant entails careful dilation. Hegar dilators (sizes 5 through 10) are preferred

manipulation. They were apparently able to create negative intra-abdominal pressure and thereby to draw in the prolapsed gut.

In acute prolapse resulting from sudden strain or from a crushing injury, the engorgement of the tissues may become so great that gangrene threatens. Reduction in such instances is a difficult problem. If the rectal wall is so friable that perforation is likely to occur, the safest procedure is an amputative operation, with every precaution being taken to avoid opening the peritoneal cavity and injuring the small bowel. If only the mucosa is damaged, gentle but firm attempts at reduction should be undertaken with the patient in the inverted position. If necessary, relaxation of the anal canal can be accomplished by the use of regional anesthesia. After successful replacement of the prolapsed gut it is well to confine the patient to bed until the supports of the anorectum have had an opportunity to resume a normal state.

When partial prolapse fails to respond to conservative management an amputative operation such as that described by Buie is indicated. If this procedure is carried out properly and if diligent postoperative care is provided, the outcome should be satisfactory.

The treatment of complete prolapse is usually surgical, necessitating obliteration of the cul-de-sac via an abdominal approach.

ANAL PRURITUS

Anal itching is a common disorder involving anal, perianal and perineal skin.

The many causes of anal itching can be grouped under three headings: systemic, local and psychogenic. Not uncommonly a definite causative factor remains undetermined. Local causes include such factors as improper anal hygiene, fungal infections, infestation with pinworms, irritation from overmedication (dermatitis venenata), irritation from ingestion of certain antibiotics, acute dermatitis, specific anal dermatoses such as psoriasis and seborrheic dermatitis, anal warts and venereal lesions.

Excess moisture, resulting from a draining anal sinus, from an anal fissure or from mucous secretions accompanying prolapsed internal hemorrhoids or rectal prolapse, may be a factor in anal pruritus. Anal itching is common during the healing of anal wounds owing probably to secretions and to the perianal stubble of hair.

Needless to say, the chief complaint is itching, which may be periodic or constant

and may vary in degree from mild to such severity that it brings the sufferer to demoralizing exhaustion.

The usual findings in pruritic anal and perianal skin are thickening, maceration and multiple excoriations. In the presence of superimposed acute dermatitis, the involved skin is reddened, there is increased local heat and there may be considerable swelling. The appearance of pruritic skin is often altered by the presence of a secondary infection resulting from the trauma of scratching. Further confusion may be added by the presence of dermatitis venenata. The physical evidence of anal pruritus is limited proximally by the dentate margin.

The diagnosis of fungal and monilial infections is confirmed by microscopic study of scrapings mounted in sodium or potassium hydroxide.

Although the examiner may occasionally see the adult pinworm on the anal skin or within the rectum on proctoscopic examination, he will usually establish a diagnosis of parasitic infestation by means of proper stool tests for ova.

A history of diarrhea and of persistent anal itching following the ingestion of an antibiotic is strongly indicative of the antibiotic as the causative agent. A bacterial imbalance of the intestinal flora is involved.

When the cause of the itching is known, the treatment is usually clearly indicated.

The difficult problem is the patient for whom no etiologic factor has been determined and whose anal itching has failed to respond to any of the conservative therapeutic measures, including fractional roentgen ray therapy.

A temporary interruption of sensory nerves can be accomplished by the injection of an oil-soluble, long-acting anesthetic agent or by an undercutting operation.

Radical treatment of anal pruritus pertains to methods by which the sensory nerve endings can be destroyed more or less permanently. These methods are alcohol injection and tattooing. Either of these methods can be used in conjunction with subcutaneous neurotomy.

PILONIDAL DISEASE

The adjective pilonidal is derived from the Latin terms pilus, meaning hair, and nidus, meaning nest. Pilonidal disease pertains here to the clinical manifestations, usually inflammatory, of pilonidal cysts occurring in the sacrococcygeal region (Fig. 91 A).

The simplest conception of the develop-

Figure 90 Diagrammatic coronal sections, modified from Tuttle, representing rectal prolapse A, Incomplete or partial prolapse B, Complete prolapse, first degree C, Complete prolapse, second degree D, Complete prolapse, third degree (Nesselrod, J P Clinical Proctology).

The concentrically arranged ridges on the surface of a completely prolapsed rectum are characteristic features, there is a striking difference between these "rings" and the radially arranged grooves or sulci seen in hemorrhoidal prolapse. Whenever there is a history of prolapse and examination fails to disclose the deformity, the patient should be asked to strain on the toilet in order to demonstrate his trouble. The nature of the condition is usually rendered quite obvious. The chief diagnostic problem is that presented by concealed prolapse. Examination of the patient in the usual inverted position fails to disclose the trouble, because the intussusception is usually reduced by such a position. It may be necessary to examine the patient while he is standing upright in order to visualize the deformity.

In infants and young children presenting partial prolapse, conservative methods are

often successful. The patient should lie down to defecate and the buttocks should be firmly strapped together during intervals between defecations. In older patients with partial prolapse it may be possible to accomplish satisfactory results with linear cauterization or with injection treatment, preferably with quinine and urea hydrochloride 5 per cent solution.

The reduction of a chronically recurrent prolapse, either partial or complete, is usually accomplished easily by the patient himself, who has long since become adept at manual replacement of the prolapsed tissue. In these instances the anal sphincteric musculature lacks its usual tone and offers little or no resistance. Oddly enough this atony facilitates both the prolapse and its reduction. Several patients with complete rectal prolapse have been observed who could reduce the prolapsed tissue without local

2. Simplicity and ease of performance.
3. Simplicity of postoperative management.
4. Correction of an overlooked limb or sinus easily accomplished.
5. Reasonable compromise in over-all time of healing.

CANCER OF THE RECTUM

Consideration of cancer of the rectum is incomplete without brief mention of precancerous tumors (adenomas) and their relation to rectal carcinoma.

A more common term for rectal adenoma is polyp; polypoid disease pertains to the entire subject of polyps or adenomas of the large bowel. It should be emphasized that any polypoid lesion of the gut must be considered potential cancer. Proof that an adenoma is benign is no security whatsoever against ultimate malignant degeneration of that lesion.

The majority of malignant lesions of the rectum are carcinomas and, of these, most are adenocarcinomas. The less common forms of carcinoma are carcinoma simplex and epithelioma.

Pathology. Adenocarcinoma is a glandular neoplasm in which acinar structures are present in varying degrees of differentiation.

In carcinoma simplex there is little or no differentiation of the glandular elements. Absence of any differentiation amounts to complete anaplasia and signifies a highly malignant process. In the scirrhous form of carcinoma simplex, fibrous tissue predominates, the tissue is hard, and there is a tendency to contracture of the involved segment of gut. In the medullary form of carcinoma simplex there is a preponderance of glandular tissue and the growth is soft.

Epithelioma (i.e., anal epithelioma) pertains to cancer of anal and/or perianal skin. Anal epitheliomas are not common. The majority are of the squamous cell type, whereas basal cell epithelioma is a rare finding.

Sarcoma is a cancer arising from connective tissue elements. Histologically such growths can be lymphosarcoma, fibrosarcoma, myosarcoma, leiomyosarcoma and melanosarcoma.

Spread of cancer occurs via lymphatics, blood stream, continuity of surface, contiguity of surfaces and, in light of recent studies, desquamation of living cancer cells.

The role of lymphatics in the spread of cancer is of great importance in the selection, planning and execution of surgical procedures for the eradication of cancer.

The newer knowledge of spread of cancer by desquamation of cancer cells stresses the need for gentleness on the part of the surgeon in handling cancer-laden tissue.

Invasion of blood vessels by rectal cancer results in dissemination via the portal venous system, leading to metastatic involvement of the liver.

Symptoms and Diagnosis. Ideally, cancer of the rectum should be discovered when it is "presymptomatic." The neurophysiology of the rectum is such that rectal lesions, early in their course, do not give rise to symptoms. Accordingly, the earliest possible symptoms of malignant disease of the rectum assume great importance. These are bleeding and a change in bowel habit.

Bleeding from the rectum must always be considered to be the result of ulceration of a malignant lesion until the contrary is proved.

A steadily progressive change in bowel habit is significant as an early symptom of rectal or colonic cancer. There may be slowly increasing constipation, a feeling of unsatisfactory defecation, frequency of stool and/or urgency of stool. Diarrhea may alternate with constipation because of perverted colonic physiology, laxatives or a combination of both factors.

Pain is likely to be a late manifestation of rectal carcinoma, unless the lesion should occur near the dentate margin with early involvement of anal tissues which, it will be remembered, possess a somatic sensory nerve supply.

Obstruction can occur rather early when a growth involves a narrow portion of the gut. The two narrowest segments of the colon are the splenic flexure and the rectosigmoid. Another factor in early obstruction by a lesion in the left colon is the firmer consistency of the content of the left colon as compared with other portions of the gut. Not uncommonly, therefore, the earliest symptoms of carcinoma of the rectosigmoid or the splenic flexure are those of obstruction.

The diagnosis of carcinoma of the rectum early in its course requires, first, a constant awareness of the possibility of such a lesion and, secondly, a thorough examination to determine the presence or absence of such a lesion.

The majority of rectal growths are within reach of the examining finger. The lesion may be a soft, polypoid mass which encroaches on the lumen of the gut but which causes little or no obstruction. This type of lesion, especially a small one, is easily missed

Figure 91 Pilonidal cyst A, Pilonidal openings in skin overlying sacrococcygeal region B, Cross section through cyst and pilonidal opening

ment of a pilonidal cyst pertains to its congenital origin as an ectodermal rest resulting from an error in developmental anatomy. The epithelial lining of the cyst and the frequent presence of hair within the cyst suggest that ectodermal tissue destined to form skin was lost in subcutaneous tissue in or near the midline.

The cavity of the cyst communicates with the surface of the overlying skin by means of one or more short channels, each opening on the skin in the midline. Thus, the lining of the cyst is in continuity at these points with skin. These are pilonidal openings, and tufts of hair are often found protruding through them.

Through the pilonidal openings, organisms commonly found on skin can easily gain entrance to the cyst. Thus are provided an infecting organism and a portal of entry.

Trauma, in all probability, is the final agent involved in pilonidal disease. This is borne out by the experience of the military surgeon who sees much more pilonidal disease than does the civilian surgeon. In both military and civilian practice, the majority of patients are in their late teens or early twenties, a time when the incidence of trauma is greatest. The incidence of pilonidal cyst is greater in males than in females.

Pain and swelling at "the base of the spine" are the chief complaints of the patient with acute pilonidal disease. The findings are those of acute inflammation (abscess) involving soft tissues dorsal to the sacrococcygeal juncture. One or more pilonidal openings are present.

In the patient whose abscess has ruptured

and drained spontaneously or has been incised for drainage, there is a draining sinus at the point of rupture or of incision. The draining sinuses are commonly to one side of the midline. The underlying tissues are indurated and only slightly tender as compared with the exquisitely tender tissues associated with an acute abscess. This patient presents pilonidal disease in its chronic stage.

An acute inflammatory process involving the soft tissues in the sacrococcygeal region, especially when pilonidal openings are found, is most likely an acutely inflamed pilonidal cyst.

Since pilonidal cysts are more commonly found in individuals who have abundant hair in the sacrococcygeal region, it behooves the surgeon to be diligent in his search for pilonidal openings in performing routine physical examinations of hirsute persons.

In the presence of chronic pilonidal disease, draining sinuses are usually found to one side of the midline and can occur lateral to the anus and even anterior to it. This may lead to some difficulty in differentiation between pilonidal disease and anal fistula. Such differentiation may have to await exploration.

The possibility of draining sinuses in this region arising from presacral tumors and cysts has been mentioned in a foregoing section.

The treatment of symptomatic pilonidal disease is surgical and comprises three methods:

1. Bloc or enucleation excision of the cyst, and primary closure
2. Excision of the cyst, leaving the wound open to heal by second intention
3. Compromise procedures such as excision with partial closure, and the exteriorization operation of Buie.

The exteriorization operation is preferred because nearly every pilonidal cyst is infected. This procedure consists of determining the extent of the cyst cavity and of all its ramifications by means of a probe or grooved director and then laying open the cavity and all its channels. Overhanging margins of skin are excised to provide a flat, saucerized wound, the floor of which is formed by the deep half of the lining of the cyst or channel. Thus healing is facilitated by the conservation of tissue which was destined to form skin. The advantages of the exteriorization operation are:

1. Wide applicability, regardless of the extent of the process.

2. Simplicity and ease of performance.
3. Simplicity of postoperative management.
4. Correction of an overlooked limb or sinus easily accomplished.
5. Reasonable compromise in over-all time of healing.

CANCER OF THE RECTUM

Consideration of cancer of the rectum is incomplete without brief mention of precancerous tumors (adenomas) and their relation to rectal carcinoma.

A more common term for rectal adenoma is polyp; polypoid disease pertains to the entire subject of polyps or adenomas of the large bowel. It should be emphasized that any polypoid lesion of the gut must be considered potential cancer. Proof that an adenoma is benign is no security whatsoever against ultimate malignant degeneration of that lesion.

Pathology. Adenocarcinoma is a glandular neoplasm in which acinar structures are present in varying degrees of differentiation.

In carcinoma simplex there is little or no differentiation of the glandular elements. Absence of any differentiation amounts to complete anaplasia and signifies a highly malignant process. In the scirrhous form of carcinoma simplex, fibrous tissue predominates, the tissue is hard, and there is a tendency to contracture of the involved segment of gut. In the medullary form of carcinoma simplex there is a preponderance of glandular tissue and the growth is soft.

Epithelioma (i.e., anal epithelioma) pertains to cancer of anal and/or perianal skin. Anal epitheliomas are not common. The majority are of the squamous cell type, whereas basal cell epithelioma is a rare finding.

Sarcoma is a cancer arising from connective tissue elements. Histologically such growths can be lymphosarcoma, fibrosarcoma, myosarcoma, leiomyosarcoma and melanomasarcoma.

Spread of cancer occurs via lymphatics, blood stream, continuity of surface, contiguity of surfaces and, in light of recent studies, desquamation of living cancer cells.

The role of lymphatics in the spread of cancer is of great importance in the selection, planning and execution of surgical procedures for the eradication of cancer.

The newer knowledge of spread of cancer by desquamation of cancer cells stresses the need for gentleness on the part of the surgeon in handling cancer-laden tissue.

Invasion of blood vessels by rectal cancer results in dissemination via the portal venous system, leading to metastatic involvement of the liver.

Symptoms and Diagnosis. Ideally, cancer of the rectum should be discovered when it is "presymptomatic." The neurophysiology of the rectum is such that rectal lesions, early in their course, do not give rise to symptoms. Accordingly, the earliest possible symptoms of malignant disease of the rectum assume great importance. These are bleeding and a change in bowel habit.

Bleeding from the rectum must always be considered to be the result of ulceration of a malignant lesion until the contrary is proved.

A steadily progressive change in bowel habit is significant as an early symptom of rectal or colonic cancer. There may be slowly increasing constipation, a feeling of unsatisfactory defecation, frequency of stool and/or urgency of stool. Diarrhea may alternate with constipation because of perverted colonic physiology, laxatives or a combination of both factors.

Pain is likely to be a late manifestation of rectal carcinoma, unless the lesion should occur near the dentate margin with early involvement of anal tissues which, it will be remembered, possess a somatic sensory nerve supply.

Obstruction can occur rather early when a growth involves a narrow portion of the gut. The two narrowest segments of the colon are the splenic flexure and the rectosigmoid. Another factor in early obstruction by a lesion in the left colon is the firmer consistency of the content of the left colon as compared with other portions of the gut. Not uncommonly, therefore, the earliest symptoms of carcinoma of the rectosigmoid or the splenic flexure are those of obstruction.

The diagnosis of carcinoma of the rectum early in its course requires, first, a constant awareness of the possibility of such a lesion and, secondly, a thorough examination to determine the presence or absence of such a lesion.

The majority of rectal growths are within reach of the examining finger. The lesion may be a soft, polypoid mass which encroaches on the lumen of the gut but which causes little or no obstruction. This type of lesion, especially a small one, is easily missed

on digital examination by the less experienced examiner

When the carcinoma has become an ulcerated, crateriform growth with firm, elevated, rolled edges and is accompanied by fixation of the involved rectal wall and by infiltration of adjacent tissues, it is almost impossible to overlook such a lesion on digital examination, provided the lesion involves the lower half of the rectum. By gradual encirclement of the gut, the growth becomes annular. Annular carcinoma of the rectum which is within reach of the examining finger feels somewhat like a nodular, lacerated cervix.

Proctoscopic examination enables the physician to verify or to qualify the findings obtained on digital exploration of the patient's rectum and to visualize those lesions which lie beyond the reach of the finger and yet within the range of the 25-cm. proctosigmoidoscope. Should obstruction preclude the passage of the ordinary proctoscope beyond the lesion, an instrument of smaller caliber can be used to complete the study and to determine the proximal level of the lesion. The distance between the anus and the distal level of the lesion or, in other words, the amount of normal bowel below or distal to the growth, is of importance in determining the type of surgical procedure best suited to the problem. As the instrument is withdrawn, the examiner can observe destruction of mucous membrane by an ulcerating carcinoma, and gangrenous tissue resulting from cancerous invasion and occlusion of the smaller blood vessels. The differentiation between a cauliflower-like polypoid lesion and an ulcerating, crateriform growth is not difficult.

Finally, proctoscopic examination facilitates removal of tissue for microscopic study. In evaluating the results of a biopsy it must be remembered that the pathologist can base his opinion on only the sample of tissue provided him. Should cancer cells be present and should invasion beneath the muscularis mucosae be demonstrated, such positive information is invaluable. Should, however, the specimen for biopsy study fail to include cancer which may be present in closely adjacent tissues, the resulting negative report could lead to a false sense of security and thus to a dangerous pitfall.

In most instances of rectal carcinoma, proctoscopic diagnosis should offer no difficulty. It is well, nevertheless, to bear in mind these possibilities for differential study: endometriosis in the female during her child-

bearing period, carcinoma of extrinsic origin (e.g., carcinoma of the ovary), diverticulitis and amebic granuloma.

Treatment. The anti-cancer campaign, with reference to rectal cancer, should begin with careful attention to the problem of rectal adenomas or polyps, which are precancerous lesions. Theoretically, at least, cancer of the rectum could be prevented if all rectal polyps were found and destroyed prior to the onset of malignant degeneration. Steadily increasing interest in proctoscopy on the part of general practitioner, internist and surgeon is a step in the right direction.

It is generally agreed that malignant lesions involving the distal 6 cm. of the rectum must be removed by abdominoperineal resection which is based on a consideration of three pedicles or zones of lymphatic spread. At levels from 6 to 12 cm. above the anus, some skilled surgeons have been able satisfactorily to perform "pull-through" operations which permit preservation of the anal sphincters and yet provide radical extirpation of the tumor with adequate lengths of bowel above and below. The studies of Waugh, in a sufficiently large number of patients, have demonstrated that five-year survival rates are at least equal to those obtained by abdominoperineal resection. In the hands of most good surgeons the latter procedure can be applied more effectively, should circumstances permit, by two teams, an abdominal team and a perineal team, working simultaneously.

Whereas the advantages of preserving the anal sphincters should not be underestimated, abdominal colostomy, established properly, can be managed and tolerated by the most fastidious patient.

Cancer above the levels mentioned can usually be resected widely and primary end-to-end (anterior) anastomosis performed. In some instances proximal decompression (temporary colostomy) may be necessary. At least 25 cm. of normal bowel distal to the lowest edge of the growth should be included in any resection. The amount of normal gut included proximal to the lesion should obviously be much greater in order to accomplish wide limits of resection for removal of lymphatic-bearing tissue.

For anal epithelioma the abdominoperineal procedure is indicated, along with dissection of both groins if inguinal adenopathy is felt to be advancing.

Palliative treatment includes colostomy for the relief of obstruction and radiotherapy for the relief of pain caused by metastatic

involvement. Chordotomy should be considered for the patient who is suffering intractable pain.

Intestinal Obstruction

By ROBERT M. MOORE, M.D.

ROBERT MILO MOORE grew up in a small town in Kansas, the son of a doctor. Educated at the University of Chicago, the University of Kansas and the medical school of Washington University, he has his surgical background in physiology. A former fellow of the National Research Council in this subject, he spent several years in the experimental surgical laboratory before he became Professor of Surgery at the University of Texas.

Intestinal obstruction remains one of the commonest and most dangerous conditions in abdominal surgery. Any serious interference with the passage of content along the lumen of the intestinal tract leads to symptoms of major severity. If the obstruction is complete, the secondary effects set in motion are intense and may result fatally in a few days' time. Only through prompt diagnosis and immediate institution of proper therapy can relief be afforded and a disastrous outcome avoided.

GENERAL CONSIDERATIONS

Since any interference with the normal downward passage of intestinal content is in reality an intestinal obstruction, a variety

of situations and mechanisms may be included under the term. At one time the word *ileus* was used to denote any form of obstruction, mechanical or functional. It has since become customary to restrict its use to those interferences which arise from abnormalities in the propulsive force of the musculature of the intestinal wall, *paralytic ileus* (also called *inhibition ileus* or *adynamic ileus*) and *spastic ileus* (*dynamic ileus*). Aside from such conditions, obstruction arises so preponderantly from mechanical lesions which interrupt the continuity of the intestinal lumen that in everyday usage the term intestinal obstruction ordinarily denotes *mechanical obstruction*.

An obstruction may be referred to as high

or low. Probably it is best to differentiate between *small bowel obstruction* and *large bowel obstruction* by using those terms and to reserve the adjectives high and low to indicate differing clinical pictures in obstructions at contrasting levels of the small intestine.

Many mechanical obstructions lead to interruption of the circulation to the intestinal loop involved, as well as to obstruction of its lumen. Such circulatory obstruction is called *strangulation* and the obstruction producing it is termed a *strangulating obstruction*, as opposed to a *simple* or *nonstrangulating obstruction*. Unless relieved, strangulation leads to gross gangrene of the affected intestinal segment. It is seen when the mesentery is twisted, as in sigmoid volvulus, or is constricted and compressed, as at the entrance to an irreducible hernia. It also occurs not infrequently in obstructions caused by adhesion bands, where a secondary torsion of the obstructed loop is not uncommon. Consequently, the surgeon must keep constantly mindful of the risk of strangulation in every patient with mechanical obstruction of the small intestine.*

A danger of necrosis and perforation, moreover, is not limited to instances of mesenteric strangulation. A number of other mechanisms which impair the circulation may develop. Necrosis from external pressure upon the wall of the bowel is sometimes noted in nonstrangulating obstructions. For example, when the intestine is trapped by an unyielding adhesion, the edematous swelling of the bowel wall at the point of encirclement may result in local gangrene. A similar necrosis is considered to be an imminent threat in the Richter type of femoral hernia. Harmful effects arising from increased internal pressure, in turn, constitute the mechanism in other cases. As distention advances, the progressive increase in the tension within the bowel lumen finally obliterates the circulation through the overlying intestinal wall. In the ordinary case of simple obstruction, anemic necrosis of the bowel wall from such excessive distention is encountered only as a late effect and in neglected patients. In any obstruction which partakes of the "closed loop" character however, a necrotizing intraluminal

pressure may develop relatively early. The designation *closed loop obstruction* refers to a situation in which the lumen of the intestinal segment is occluded at both ends so that there can be neither downward passage nor regurgitation. Thus, in the loop intervening between two separate mechanical obstructions, no means is provided for escape of contents in either direction. The majority of strangulated loops fall into this category, for example, in volvulus there is occlusion of the lumen of both afferent and efferent limbs and the same situation ordinarily exists in strangulated hernia. However, the closed loop concept has its foremost clinical application in relation to colon obstructions.

Other terms used in differentiating types of intestinal obstruction are *acute* and *chronic obstruction*, and *complete* and *partial* obstruction. An obstruction is termed *chronic* when it has been partial or intermittent or when there have been recurring episodes or threats of obstruction. Since any obstructive episode is an immediate menace to the individual, it is safest to consider all obstructions or threats of obstruction as *acute* until relieved. Too often the term chronic obstruction lulls the surgeon into a false sense of security in dealing with obstructions having an insidious onset, as do, for example, certain obstructions of the large bowel.

A broad classification of intestinal obstruction might include three groupings: *mechanical obstruction*, both simple and strangulating, *neurogenic obstruction* or *ileus*, and *vascular obstruction*, this last referring to the relatively infrequent obstructions arising from embolism or thrombosis of a main mesenteric vessel, such as the superior mesenteric artery. As has been noted, the vascular occlusion seen in the local mesenteric sector which has been twisted by a volvulus, or compressed in a hernial ring or in an intussusception, is secondary to a mechanical force which has obliterated both the intestinal lumen and the local vessels. *Vascular obstruction*, in distinction, refers to an intestinal obstruction which has resulted from a primary vascular disease, or "vascular accident." The principal effect upon the intestine is a complete or nearly complete denial of blood supply, ordinarily to a loop of great length. In occasional patients, the arterial occlusion is *partial* so that the affected bowel regains sufficient circulation to escape gangrene. Even in such patients, however, there is an interim which

* Modified from Wangenstein in Christopher: A Textbook of Surgery, 5th ed.

the intestine is unable to perform its muscular functions. Forward propulsion ceases as a result and the loop becomes dilated.

do most cases of so-called paralytic ileus, since the latter generally are due to excessive nervous inhibition of the intestinal muscle rather than to a real loss of muscle power.

A detailed classification based on the clinical and pathologic types of intestinal obstruction is given in Table 10. While in practice the type of obstruction is well defined clinically in many cases, in others an accurate differentiation may be difficult or impossible. The clinical picture results from a combination of primary and secondary elements. Furthermore, the characteristics of an obstruction often are changing because of the factor of elapsed time since onset of obstruction. An obstruction which begins as a simple obstruction of the lumen of the intestine may become a strangulating obstruction as distention develops and added

mechanical factors come into play. Therefore, despite the usefulness of a detailed classification, it is important to remember that an obstruction may change its character. Treatment must be governed accordingly and whenever operative measures are deferred on the basis that an obstruction is of the simple or nonstrangulating variety, the possibility of strangulation having intervened must be reassessed at frequent intervals.

MECHANICAL OBSTRUCTION

Some of the mechanisms by which the intestine may become obstructed are illustrated in Figures 92 and 93. Data upon the relative incidence of the various causes of obstruction vary greatly, depending upon the age and sex of the clientele of the hospital or surgeon reporting. In a children's hospital, many newborn babies and infants are treated for intestinal obstruction arising from such congenital anomalies as atresia, stenosis, intestinal malrotation and congenital hernia. Of these congenital causes so fre-

most commonly in the ileum or in the duodenum. Discontinuity of the lumen of the large intestine occurs chiefly at the rectum (imperforate anus). D, Compression by an *extrinsic* tumor. The pelvic colon may be compressed, for example, between a tumor and the rigid bony wall of the pelvis. Such obstruction usually is incomplete.

quent in babies, only strangulated inguinal hernia also serves as a common mechanism to cause obstruction in adults. Intussusception, which is not related to any congenital anomaly, is another frequently occurring type of obstruction during the earliest years of life.

Approximately two-thirds of all obstructions arise either from strangulation in hernias or from acquired or congenital adhesion bands, these types of obstruction being common at all ages. In men, strangulation of inguinal hernia is most frequent as opposed to strangulation of femoral or of umbilical hernia in women.

As individuals pass middle age, the incidence of obstruction caused by cancer increases greatly. Cancer of the intestine, except for secondary lesions, is almost always

situated in the colon. This is borne out by the observation that while carcinoma accounts for only about 10 per cent of all intestinal obstructions, it causes approximately 70 per cent of the obstructions of the large bowel. Next in frequency to carcinoma in causing colon obstruction is volvulus of the sigmoid, which accounts for perhaps one out of six of the acute obstructions of the large bowel. Aside from ileocolic intussusception in small children and the occasional case of imperforate anus in the newborn, large bowel obstruction is relatively rare in the younger age groups.

Physiopathology. Any mechanical obstruction to the normal downward passage of content within the intestinal lumen leads to developments of an emergency nature. Since the ingestion of food can be interrupted for

weeks before life is threatened, the pressing dangers of intestinal obstruction obviously are not related to starvation. In strangulating obstructions the immediate threat is readily apparent, if the strangulated loop is left in situ until necrosis and dissolution occur, overwhelming peritonitis almost certainly will follow. In simple or nonstrangulating obstructions, in contrast, dangers which are very real are at first glance much less obvious.

Whenever the forward propulsion of content is blocked by occlusion of the intestinal lumen, a sequence of local reactions is set in motion. These local changes and their systemic sequelae account for the critical symptoms and the rapid death attending neglected simple obstruction. The primary lethal processes have been identified by frequent clinical demonstration that when strangulation is absent the patient's condition usually can be maintained for several days without great deterioration provided two requirements can be met. First, distention of the proximal intestine must be prevented and, second, dehydration and electrolyte loss must be

corrected effectively by parenteral replacement. Therefore the immediate dangers in nonstrangulating obstruction stem from *distention* and *water and electrolyte loss*. The triad of primary lethal effects of mechanical obstruction will be completed should *strangulation* enter the picture.

The initial local response to obstruction of the intestinal lumen is a marked increase in *peristaltic activity* in the loop just proximal to the obstruction. As this intestinal segment attempts to drive its contents past the obstructive barrier, the waves of peristalsis become progressively more forceful and violent. They are the source of the sharp intermittent or cramping pain—the “colic” which leads the clinician to suspect that an obstruction is present.*

* Colic, or intermittent pain synchronous with recurrent waves of abnormally violent peristalsis, is a characteristic symptom of obstruction of any tubular passage having walls of smooth muscle. Painful contraction waves corresponding to those in the obstructed intestine occur regularly when a stone blocks the ureter (ureteral colic) or a bile duct (biliary colic) or even, as occasionally happens, the appendix (appendiceal colic).

Figure 93 Common mechanisms of intestinal obstruction A, *Volvulus*, or twisting of an intestinal loop, may result from congenital anomalies (an example is the midgut volvulus of an incompletely anchored mesentery) or may develop later in life (volvulus of a redundant sigmoid colon in the adult) B, *Narrowing from congenital stenotic areas* in the newborn. Acquired structures may be inflammatory, as in sigmoid diverticulitis, or neoplastic, as in carcinoma of the colon. C, *Obturation*. Rarely the intestinal lumen becomes blocked by a foreign body, by an enterolith or by a mammoth gallstone which has ulcerated its way from the gallbladder into the duodenum. D, *Intussusception*, or the telescoping of a proximal loop of intestine into a distal loop. In infants, over 90 per cent of intussusceptions are of unknown origin or idiopathic. At any age a polyp or other intestinal tumor may serve as the “leading point” to initiate intussusception.

By this abnormally increased peristaltic activity, the intestine actually traumatizes itself and the edema of the intestinal wall which follows is to some degree a result of this injury. Proximal to the point of obstruction, edema may be masked by the thinning effect of distention, but at the point engaged in the obstruction there is actual swelling. Since any thickening of the wall at this point must be at the expense of the narrowed lumen, the edema often serves to render complete an obstruction which was only partial at its onset. Furthermore, it frequently contributes significantly to the irreducibility of the obstruction.

Distally the intestine lies empty, contracted and inactive, while proximal to the obstruction there is a rapid accumulation of bowel content. For the resulting *distention* to be marked, it is not necessary for oral intake to continue. Under ordinary circumstances the gastrointestinal tract secretes daily into its lumen as much as 8 liters of digestive fluids and this secretion continues in part even when nothing is ingested. Normally, reabsorption is at such a rate that only a small volume of water (100 to 150 cc) is lost in the stool. Obstruction upsets this balance, however. Secretion into the intestinal lumen may actually be increased, whereas the normal absorptive power is significantly lacking. This combination of increased secretion and defective absorption is typical of overdistended intestine.

The degree of the distention of the proximal intestine depends, of course, upon the completeness of the obstruction and upon the time which has elapsed since its onset. Although dilatation is greatest immediately above the obstruction, the entire proximal tract eventually becomes involved. Except in obstructions located high in the jejunum, the aggregate volume of the distended coils is sufficient to create a serious problem in abdominal distention, the tightly expanded abdomen interfering mechanically with such vital functions as respiration and venous return.

Often the obstruction represents an abnormal point of fixation in the small intestine and the weight of the distended proximal loop results in its sagging at this point to superimpose acute *angulation* as an added obstructing mechanism.

The content of the distended intestine is both liquid and gaseous. The liquid element is made up of accumulated secretions, food residues and the products of bacterial multiplication. The gas, as shown by many meas-

urements, consists largely of *swallowed air* (70 per cent). Both nausea and thirst aggravate the patient's tendency to swallow air. Air is in great part nitrogen (80 per cent), an inert gas which is absorbed extremely slowly. As a consequence, air swallowing is a major factor in abdominal distention. Only by the use of some decompressing device which recovers the air immediately as it is swallowed can distention be prevented.

In unrelieved intestinal distention, the progressive increase in intraluminal tension interferes eventually with the flow of blood through the wall of the bowel. Usually the anoxia affects the mucous membrane first, the submucosal vessels being particularly vulnerable to the flattening force exerted by the pressure from within the lumen. There is increasing edema which may be followed by actual necrosis, even of the entire thickness of the wall. Such necrosis from excessive intraluminal tension can be observed in the experimentally produced closed loop of intestine (a segment which has been occluded at both ends by suturing). It is also seen occasionally as a late event in patients with neglected simple small bowel obstruction. Its greatest practical importance, however, lies in the necrosis and "spontaneous rupture" which may be encountered relatively early when complete obstruction of the left colon occurs in patients having a competent or "one-way" ileocecal valve. In this important group of patients, the development of obstruction distal to that valve amounts to completion of a closed loop, since the intervening bowel thus becomes shut off at both ends. Even though the secretions of the colon are not bulky, the formation of putrefactive gases and the continued entry of content from the ileum may combine to distend the loop until the intraluminal tension is dangerously high. Such patients demand prompt decompression by operation in order to avoid the risk of necrosis and perforation.

In all acute abdominal disorders, there is apt to be an initial reflex emptying of the stomach. In intestinal obstruction, the vomiting continues, however, and tends to be frequent and copious. It may be brought on

* Prior to such decompression, care must be exercised not to administer diagnostic barium enemas under excessive pressure. Distention of the rectum normally evokes reflex peristaltic contraction of the colon, and "spontaneous rupture" of the distended bowel, usually at the cecum, may be precipitated by the violent reflex contraction evoked when the rectum is overdistended.

by attempts to ingest food or drink and it occurs typically after a crescendo of painful peristaltic contractions, reversal of flow having finally regurgitated intestinal content into the stomach, which then ejects the material.* This regurgitant nature of the vomiting in obstruction is illustrated by the frequent observation that when the obstruction is high in the small intestine the vomiting begins early, whereas its onset often is delayed when the obstruction is at a lower level. Moreover, vomiting may be entirely absent in colon obstructions.

In late cases of intestinal obstruction, the distended and thin-walled proximal loops lose all effective contractile power. The colicky waves of peristalsis diminish in vigor at this stage and often the vomiting amounts only to the stomach's emptying itself of a passive overflow from the distended intestine. The vomitus may be dark and odorous and this has given rise to the term fecal vomiting. Such vomitus, however, usually does not come from the colon but represents the results of stagnation and bacterial multiplication in the dilated small bowel.

A number of mechanisms take part in the severe *water and electrolyte loss* characteristic of advanced intestinal obstruction. The deficit from interruption of oral intake and the loss from vomiting are readily apparent and require no detailed comment. Less obvious, but equally significant, are certain internal or hidden depletions.

Since the absorptive power of the intestinal mucosa becomes increasingly defective as distention develops, gastrointestinal secretions which are poured into the obstructed intestine often are lost to the body just as effectively as are those which are vomited. Furthermore, the dilatation of the bowel may serve by irritation actually to increase the flow of secretions. In low obstructions, as a consequence, the proximal intestine fills with an accumulation of water and essential electrolytes which is of no avail whatever to the body. In this situation, dehydration and electrolyte loss may be well under way even before the advent of vomiting.

At an early stage of obstruction, a sizeable *loss of plasma* may be in process. This loss, which consists in the escape of protein-containing transudate through the edematous wall of the intestine and into the peritoneum,

* Although *reversed peristalsis* has been observed in the duodenum, it is the consensus that in lower obstructions regurgitation actually is the result of normally directed peristaltic waves which force the intestinal content against the obstruction until finally the stream reverses itself to surge proximally

increases dehydration and adds the element of protein depletion.

In the relatively infrequent obstructions arising very high in the small intestine, the vomiting tends to be immediate and constant and results in an imbalance approaching somewhat that seen in pyloric obstruction. Dehydration, being accompanied by a greater loss of chloride ion than of sodium, results in hypochloremia and an alkalosis which is evidenced by elevation of the carbon dioxide combining power of the blood. In obstructions at lower levels, the vomiting is usually intermittent and less copious at the start, and since the loss of sodium ion equals or exceeds that of chloride ion the patient is prone to develop an acidosis unless there has been adequate parenteral replacement. In patients with neglected obstruction at either level, severe dehydration leads to hemoconcentration and to oliguria, and often renal damage is reflected in an elevated nonprotein nitrogen in the blood. Potassium deficiency is another complicating factor in late cases, as is also the sizeable loss of plasma through the bowel wall. The presence of hemoconcentration tends to mask these deficits and laboratory data must be interpreted with this effect in mind.

In simple obstruction, the intestinal wall is reddened and edematous, although the thinning effect of distention may make the edema less apparent. The distended loop often "weeps" so that a serous transudate collects in the peritoneum. If the obstruction produces *strangulation*, the affected loop shows the changes of hemorrhagic infarction. Its color varies from gray to bluish black depending upon the degree and duration of the vascular involvement. Ordinarily the veins are occluded first by the strangulating force and for a time the systolic pressure continues to drive arterial blood into the congested intestinal wall. There is a consequent rupture of venules with blood escaping into the intestinal lumen, sometimes in a quantity sufficient to cause hemorrhagic shock. There may be a similar escape of blood from the serosal surfaces of the strangulated intestine and mesentery so that the peritoneal fluid takes on a sanguineous character. Finally, the mounting tension within the lumen of the strangulated loop stops all capillary circulation in the wall and frank gangrene follows. At this stage, the arteries as well as the veins of the involved mesenteric sector have become thrombosed and release of the loop from the strangulating mechanism no longer restores their pulsa-

tions The gangrenous intestine soon perforates, but even before gross perforation is evident the necrotic wall has served as a portal through which bacteria and toxic agents have escaped into the peritoneal cavity

The escape of bacteria and toxins through the wall of the gangrenous intestine contributes the final, and most deadly, threat in intestinal obstruction. Once this stage is reached, the mortality rate will be formidable no matter how energetic and skillful the treatment. It is borne out by long experience of surgeons that intestinal resection necessitated by gangrene of an obstructed loop carries much greater risk to life than does intestinal resection performed for other reasons. The difference, of course, arises from the fact that, by the time gangrene has developed, the peritoneum has already been subjected to a heavy dose—perhaps a lethal dose—of noxious contamination by agents set free from the intestinal lumen

When gangrenous intestine disintegrates within the abdominal cavity, the intestinal content pours into the peritoneum. With rare exceptions, the contamination becomes generalized and the outcome is overwhelming peritonitis. In that third or more of obstructions which are caused by strangulated hernias, however, the strangulated loop does not lie within the abdomen proper but in a separate peritoneal sac or compartment. In these cases, there is the possibility that at the narrowed neck of the hernia the natural defenses will succeed for a time in confining the contamination to the hernial sac and that during this time peritonitis will remain localized. However, one can never rely on such localization, even temporarily, and hence there is necessity for prompt surgical intervention whenever strangulation is suspected.

The harmful effects of bacterial activity in intestinal obstruction are not limited to this late phase of peritonitis following bowel necrosis. Bacteria are also influential in earlier developments. Their mere multiplication in the stagnant content of the obstructed intestine contributes to distention by adding the bulk of bacterial growth as well as the gases created by their action. Bacterial activity also augments the liquid content since it increases intestinal secretion, an effect evidenced by demonstrations that, in experimentally produced closed loops of intestine, agents which inhibit bacterial activity serve to diminish secretion. Finally, bacteria play an important role in initiating

and accelerating the gangrene which results from strangulation. There have been repeated demonstrations that control of bacterial activity through intestinal antiseptics delays and limits tissue necrosis when a loop is partially devitalized. Bacterial invasion of the bowel wall is a potent factor in causing venous thrombosis to precipitate tissue death. This is particularly telling in areas where blood supply is deficient but not entirely lacking. In such marginal and less extensive areas of defective circulation, collateral blood supply can sometimes be established in time to avert actual gangrene if invasion by bacteria can be prevented in the interim.

It has always been difficult to understand why certain patients die from simple, or non-strangulating, obstruction. As a consequence, a *toxemia theory* has often been proposed to explain such deaths on the basis of perverted absorption from damaged intestine. Thus, for example, systemic effects were attributed at one time to products of protein breakdown not absorbed in the normal bowel. Histamine and histamine-like substances were suggested particularly as responsible toxins. Although experimental tests have failed consistently to identify any specific substance, certainly the possibility exists that when intraluminal tension is greatly elevated the blood vessels and lymphatics of the edematous bowel wall may take up products which are toxic systemically. There has been little positive evidence, however, that such absorption is actually appreciable so long as the layers of the wall retain their viability. Too often the symptoms arising from severe dehydration and electrolyte losses have been attributed to a conjectured toxemia.

Once the viability of the intestinal wall is impaired, the situation is radically different. Necrotic tissue then offers an easy avenue for direct escape of bowel content into the peritoneum. Absorption through a serous membrane, such as the peritoneum, is much less selective than is absorption through the intestinal mucosa and there is little doubt but that many toxins of bacterial and non-bacterial origin are readily absorbed by the peritoneum. Consequently, fever and toxemia are no longer a mystery once there is gangrene and peritonitis.

In summary, from the standpoint of the pathologic processes which endanger the life of the patient as a result of intestinal obstruction, one can conclude that so long as the circulation through the intestine is intact the chief dangers from obstruction of the

lumen lie in the water and electrolyte losses and in the mounting intestinal distention. If distention progresses unrelieved, the intraluminal tension may eventually become increased to the point that the viability of the bowel wall is impaired. Bacterial influences then join in posing the threat of necrosis with perforation and peritonitis. Fortunately, except in closed loop cases, this stage is encountered infrequently in simple, or nonstrangulating, obstruction and only as a late event. In strangulating obstructions, in contrast, circulatory impairment constitutes the immediate danger. Although obstruction of the lumen usually precedes occlusion of the vessels, it is the latter which leads to irreversible gangrene, sometimes within a period of hours. Properly, then, whenever there is a threat of strangulation that danger takes precedence over all others.

Diagnosis. The diagnosis of acute intestinal obstruction is based upon the symptom triad: *cramping abdominal pains, vomiting and failure to pass gas or feces by rectum.* Although distention becomes of great significance as obstruction advances, in the initial stages of small bowel obstruction, when diagnosis is particularly to be desired, distention may be slight and does not afford a dependable diagnostic criterion.

The clinical picture of acute intestinal obstruction is seen in its typical form when the *small intestine* becomes obstructed. The patient, an individual of any age who may or may not have experienced a similar previous episode, is seized rather suddenly with *cramping abdominal pains.* These pains, which are synchronous with waves of forceful peristalsis, are usually felt neither to the right nor to the left but in the midabdomen, or "pit of the stomach," at the level of the umbilicus or higher. The patient is apt to describe them as "gas pains," or "colic." They are intermittent, recurring in a series of waves or paroxysms. Each painful cramp characteristically builds up to a peak of intensity and then subsides. Similarly, it is not infrequent for the cramps in a sequence to mount in a crescendo fashion and then to taper off. In the earlier stages of obstruction, the patient does not appear particularly ill in the intervals between these pains, unless, of course, as in some obstructions arising during a postoperative period, the patient is already quite sick at the time obstruction develops.

The earliest paroxysms of abdominal pain usually followed immediately by vomit-

ing. The first vomiting is neurogenic in nature, the stomach emptying itself on reflex stimulation as it does at the onset of many acute abdominal disorders. The vomitus consists of whatever the stomach happens to contain. Following this initial reflex emptying of the stomach, there is a variable interval before vomiting resumes in the regurgitant form which is typical of intestinal obstruction. So long as no additional material is taken by mouth, the length of this interval of freedom from vomiting depends largely upon the level of the obstruction. Proximal to the obstructed point, as noted previously, the intestine becomes distended with fluid and gas which it has been unable to drive forward. The powerful peristaltic contractions by which it attempts to force its content past the obstruction soon culminate in periods of reversal of stream which regurgitate this material proximally. In high jejunal obstruction, as a consequence, there may be little or no pause in the vomiting since the stomach soon is ejecting the content regurgitated from the uppermost intestine. When the obstruction is low in the ileum, in contrast, there may be a considerable interval before reflux reaches the gastric level. As regurgitant vomiting begins, the vomitus is at first bile stained by duodenal content. Then it becomes the thin brownish or greenish content of the distended small intestine. Late in obstruction the material vomited becomes thicker and foul smelling.

Although *failure to pass gas or feces by rectum* soon follows the development of an obstruction, there may be one or more initial movements as the distal bowel empties out its content. In like manner, enemas given to encourage evacuation may at the start return fecal matter and gas which had already reached the colon. Once the intestine distal to the obstruction has been emptied, however, evacuation comes to an end. Thereafter, no gas is passed, provided, of course, that obstruction is complete. This point is of great practical importance in the observation of patients having threatened or suspected obstruction, continued passage of gas by rectum being a reliable indication that any obstruction present is but partial.

These three symptoms, colicky pain, vomiting and failure to pass gas or feces, are the essential evidences of intestinal obstruction. Some of the additional manifestations are important though less dependable because of their variability. The most constant observation on physical examination is an increase in peristaltic sounds. Borborygmi

are heard at the height of the intermittent pains. Occasionally the sounds become so loud as to be audible without the aid of a stethoscope and the patient may even report that he hears the noises himself. The sounds are often of a gurgling or bubbling quality and sometimes the movements of intestinal content can be detected by palpation. As distention increases, the sounds take on a higher pitch and assume a metallic or tinkling character. However, since loud peristaltic sounds are often heard in the absence of any distinct pathologic process, the borborygmi heard in a patient with suspected obstruction must be interpreted with caution. Probably such sounds are of no particular significance unless they are synchronous with the peaks of the colic. In that case they serve only to establish the presence of hyperperistalsis or colic. It must still be determined whether the colic in the particular instance at hand results from a mechanical obstruction of the intestine or from an acute intestinal irritation such as from gastroenteritis or food indiscretion. In either instance, however, the fact that the abdomen is not silent but that peristaltic activity is readily audible with the stethoscope aids in diagnosis in that it tends to rule out paralytic ileus, an important condition which also is accompanied by distention, vomiting and constipation, but in which the abdomen is relatively silent.

Inspection of the abdomen may show only the slight fullness of early *distention*. Of course, the abdomen will be tight and protuberant if distention has become advanced and there will then be marked tympany on percussion. An external hernia may be visible on inspection, and palpation may prove that it is irreducible, tense and tender, so as to suggest immediately a diagnosis of strangulated hernia. In nonstrangulating obstructions, however, abdominal palpation ordinarily gives negative findings. Although the patient may voluntarily draw up his knees and tighten his abdominal muscles during a cramping paroxysm, examination during one of the pain-free intervals usually reveals neither rigidity nor definite tenderness.

It has already been noted that in the earlier stages of simple obstruction the patient does not appear particularly ill, except during the seizures of pain. Marked systemic changes are absent and the laboratory is of little help. The temperature is normal and the pulse rate is not materially increased. There is no significant leukocytosis and the water and electrolyte losses have not yet

been sufficient to be reflected in chemical determinations. Of the various special procedures, only the *roentgen ray* examination of the abdomen is commonly of aid in establishing the diagnosis and in certain instances is of the greatest help. In other cases, however, roentgen ray findings are inconclusive and supply only presumptive evidence. This is particularly true in patients in whom differentiation between mechanical obstruction and paralytic ileus proves especially difficult. In problem cases such as these, the roentgen ray findings must always be correlated with the clinical observations. Again one returns to the conclusion that for intestinal obstruction to be recognized in its early phases when release can be accomplished most efficiently and at the minimum of risk to the patient, the diagnosis usually must rest upon the cardinal symptoms previously mentioned: cramping abdominal pains, vomiting and failure to pass gas or feces.

Late in intestinal obstruction, systemic effects are readily apparent. They consist chiefly of the physical signs of advancing dehydration. Laboratory studies reveal the resulting concentration of the blood. However, the dry skin and tongue, the sunken eyes, the scant and concentrated urine and the hemoconcentration, which the laboratory reports after copious vomiting has been in progress for several days, are in no way specific signs peculiar to intestinal obstruction. They are merely evidences of untreated dehydration, indicating the lack of adequate replacement therapy during a period when there has been excessive fluid loss from any cause.

In some instances, the advent of *strangulation* in small bowel obstruction produces sudden and dramatic developments which are easily recognized. Immediately, the abdominal pain becomes more severe and takes on a constant rather than intermittent character. The

in the back.
becomes that of a severe shock, varying degrees of circulatory collapse or shock develop, with lowered blood pressure, accelerated pulse and subnormal temperature. In abrupt and massive strangulations, shock is particularly apt to be immediate and profound. Along with these circulatory changes, there are distinct alterations in the abdominal picture. Localized tenderness develops and the strangulated loop often becomes palpable as a tender, indefinite mass. Roentgen ray examinations may

tended loop to be discrete and to have an unusually smooth-edged appearance, the corrugations caused by the valvulae conniventes having been lost. Leukocytosis and fever develop, and there is mounting rigidity to indicate peritonitis.

When the onset of strangulation is heralded by such changes as these, the surgical emergency is obvious. Unfortunately, however, in many other patients, strangulation develops rather insidiously without striking and abrupt changes in the clinical picture, and in such patients its early detection may be exceedingly difficult. This fact greatly complicates the frequent problem of proper management of the patient in whom marked distention and advanced water and electrolyte imbalance are already present when he is first seen by the surgeon. In this situation, delay in operative intervention for a day or longer while these complications are righted might well serve the patient's best interest, but only provided the surgeon can be certain that strangulation is neither present nor impending. To aid in this dilemma, many studies have been made with the purpose of establishing dependable criteria so that strangulation can always be recognized immediately and accurately. Increased pain and pain of a constant type, increased pulse rate, the presence of a mass, tenderness, leukocytosis and beginning abdominal rigidity are signs of strangulation most commonly cited. With such points in mind, some experienced surgeons find that they are able to diagnose strangulation with satisfactory accuracy, while others report much less success in this regard. Moreover, it should be pointed out that any emphasis placed upon the early signs and symptoms of strangulation must not be interpreted to mean that all is well so long as one proceeds with operation as soon as strangulation is recognized. To the contrary, it can scarcely be denied that the surgeon does much better by his patient if the intestinal loop can be released before gross impairment of circulation has occurred, not after. Although the release of a strangulated loop may be followed by changes in the appearance attesting its viability, in many instances this is not the case and resection becomes necessary in an extremely ill patient. It is well to emphasize that a number of the so-called signs of strangulation actually are signs of inflammation; that is, they are the signs and symptoms of the peritonitis which is developing as a result of strangulation.

Generalizations regarding diagnosis are

apt to be misleading in *colon* obstructions because these present a wide variety of clinical pictures, ranging from the dramatically sudden onset and rapid course of sigmoid volvulus to the slow, insidiously developing obstruction often seen in association with carcinoma of the colon.

Only in the sigmoid, which has a long mesentery, is volvulus common. Elsewhere in the colon mobility is so limited by the peritoneal and omental attachments of the bowel that twisting with resulting strangulation is rare. Furthermore, because of the limited mobility, colon loops seldom enter hernial orifices (except "sliding" hernias) or pass through windows between peritoneal bands. Instead, in the case of the colon, obstruction usually results from a disease of the bowel itself. Carcinoma, or less commonly chronic inflammatory disease, slowly blocks the bowel lumen by stricture formation or by a combination of obturation and stricture. The block becomes complete only after the disease has been present for a considerable time. Clinical obstruction, therefore, often develops gradually or with recurring episodes or threats of obstruction. The episodes become progressively more severe. Often the surgeon does not see the patient until he has finally become completely obstructed and is in a distended, cramping state amounting to that of an acute obstruction. If there is a competent ileocecal valve, extreme distention of the colon may develop rapidly with great danger of necrosis and perforation as a result of excessive intraluminal tension. There may be no vomiting whatever. In other adults, and in almost all small children, an incompetent valve permits reflux into the small intestine and the colon is protected to some extent against a sudden and excessive rise in pressure within its lumen. Even in these patients, the vomiting may be greatly delayed and scant. In partial and intermittent forms of colon obstruction, the small intestine may gradually become greatly distended over a time and patients sometimes present themselves with an enormously distended abdomen which has caused surprisingly little discomfort or vomiting.

In view of the commoner causative lesions, patients with large bowel obstruction are apt to be in the older age group and to show such evidences of an underlying chronic disease as anemia and protein depletion. The patient often reports a change in bowel habit dating back some weeks or months, followed by increasing difficulty from con-

stipation or by alternating bouts of constipation and diarrhea. He has cramping pains, often lower in the abdomen than is the case in small bowel obstruction. He is distended, usually markedly so, and there is pronounced tympany on percussion. An intestinal "pattern," with visible peristalsis is not uncommon. Peristaltic noises are audible and these may be low pitched and rumbling. Vomiting may have been scant or absent and there may be little evidence of dehydration. The roentgen ray "scout" film portrays the distended colon and, as described below, fluoroscopy with the barium enema reveals the location of the obstruction.

In comparing the diagnostic criteria with those in obstruction of the small intestine, the chief contrasts lie in the frequent absence of vomiting in colon obstruction and in the earlier appearance of meteorism or distention in many patients. In view of these differences, the symptom triad given for obstruction of the small intestine might well be altered in the case of large bowel obstruction to read: *cramping abdominal pains, distention and failure to pass gas or feces by rectum.*

Roentgenographic Studies. Although, in the final analysis, the diagnosis of intestinal obstruction must depend upon clinical fea-

tures, radiographic studies of the distribution of gas within the abdomen and of the configuration of the gas-filled intestinal loops are often of great aid in diagnosis. In the normal abdomen, except in infants and very small children, gas is visualized on roentgen ray film only in the stomach, duodenal bulb and colon. Within the small intestine, the bowel activity keeps the gas too intimately mixed with the content for it to be visible. When there is marked stasis for any reason, however, the gaseous and liquid elements separate and then the gas collections become visible on the roentgenographic film. In the patient with intestinal obstruction, for example, within six hours after onset roentgen ray studies will usually portray the pockets of separated gas and thus serve to locate the intestinal loops which are proximal to the obstruction. Moreover, as the distention of an individual loop progresses, the increased content of gas serves to delineate the intestinal walls bounding the gaseous accumulation and thus provides useful information regarding the contour and configuration of the loop.

A roentgen ray picture, taken with the patient sitting or erect, may show multiple fluid levels of the type characteristic of mechanical obstruction (Fig. 94). In other

of the proximal

cases, the typical stepladder pattern (Fig. 95) may be seen. Survey or scout films taken with the patient in a horizontal position are particularly useful in revealing the location and contour of the dilated loops. A loop of distended colon can often be distinguished by virtue of its haustral markings and its position and course within the abdomen (Fig. 96). Distended loops of small intestine tend to show the distinguishing transverse markings of the valvulae conniventes, exaggeration of the normal "feathering" often producing the effect known as the accordion or herringbone appearance (Fig. 94). When a distinct loop of small intestine loses these valvular markings and shows smooth rather than corrugated margins, strangulation is to be suspected.

Sometimes the x-ray appearance is so typical that it permits identification of the mechanism causing the particular obstruction. For example, the contour and position of the limbs of the twisted loop of the sigmoid colon are often so characteristic as to permit a diagnosis of volvulus from the roentgen ray view alone (Fig. 97). Other peculiar configurations seen on roentgen ray film aid in the diagnosis of intussusception and of malrotation.

In some instances, the radiographic confirmation and portrayal of an intestinal obstruction are facilitated greatly by concomi-

tant administration of barium as a contrast medium (Fig. 98). When the barium is administered as an enema by rectum, its use is safe provided due care is exercised to avoid overdistention of the rectum by the balloon commonly used and overdistention of the large bowel as a result of administering the enema under excessive pressure. Such precautions are necessary lest perforation be

Figure 98. Appearance with barium enema in a patient with carcinoma of the splenic flexure of the colon. The column of barium often stops completely when the tumor is first encountered but passes through the narrowed area shortly thereafter to delineate the defect. (Illustration drawn from an x-ray view.)

caused in patients having colon obstruction, either as a direct effect, the bowel perforating at a diseased area which is subjected to the immediate pressure of the enema, or indirectly owing to an excessively violent reflex contraction of the proximal colon having been elicited by distention of the rectum. In the latter instance, the thin-walled cecum proximal to an obstruction may "rupture" itself if the ileocecal valve is competent. However, when performed in a safe manner, the barium enema is so helpful in demonstrating the presence and location of a large bowel obstruction that it is considered an essential part of the preoperative study in colon obstructions. Without the information it provides, the surgeon often would be unable to plan the operation and the surgical approach intelligently.

Aside from its negative value in demonstrating that the colon is not obstructed, the barium enema is of little aid in the study of obstructions of the small intestine, excepting those involving the immediate vicinity of the ileocecal valve such as terminal ileitis and ileocolic intussusception. This has given rise to the temptation to administer the barium by mouth in obstruction or suspected obstruction. However, when barium is introduced proximal to an obstruction it has a notorious tendency to form an impaction at and above the point of obstruction where it frequently becomes inspissated to form a hard mass or enterolith. The impaction immediately converts a partial obstruction into a complete one and the barium mass greatly complicates the surgical treatment. With few exceptions, consequently, the oral administration of barium in patients with possible intestinal obstruction is to be condemned. Such use has led to many deaths in persons having colon obstruction through operative and postoperative complications for which the barium is responsible. Moreover, in obstruction at more proximal levels, oral administration of barium is usually unnecessary and the information to be gained by its use is seldom worth the risk involved. In the highest obstructions, pyloric and possibly duodenal, the cautious use of small quantities of a thin barium mixture may sometimes be permissible if one is sure he can recover the barium in washings. Even here, however, one must weigh the advantages against several risks. The latter include the risk of aspiration of barium into the lung, a particular danger in the infants in whom these very high obstructions are most common.

Differential Diagnosis. The conclusion that

obstruction is present in a given patient immediately poses several supplemental problems in diagnosis. Information bearing upon the degree, the approximate site and the probable cause of an obstruction provides a basis for intelligent estimates relating to the urgency of the situation, the course to be expected and the likelihood of early strangulation.

So long as the patient continues to pass gas by rectum, the obstruction may be considered to be only threatened or partial. Similarly, roentgen ray demonstration that gas reappears in the colon after it has been evacuated by enemas indicates that the obstruction is still incomplete. Since complete occlusion of the intestinal lumen nearly always precedes the advent of strangulation,* continued passage of gas leads to the conclusion that time is available for additional study as well as for attempts to relieve the obstruction by nonoperative means.

The approximate site or level of an obstruction can often be conjectured on the basis of the history and symptoms. Moreover, an obstruction of the colon can ordinarily be located accurately by means of the fluoroscope and barium enema, whereas the x-ray scout film often serves to locate a small bowel obstruction within the limits of the upper, middle or lower third of the small intestine. Even this approximation as to location permits a more intelligent selection of incision.

In some patients the specific cause of an obstruction is obvious on physical inspection. This is the case in strangulated external hernia or in imperforate anus. Other patients in whom the physical signs permit a strong inference as to cause include those with laparotomy scars to suggest obstruction by adhesions, or with a palpable tumor which is characteristic, as in intussusception. Again, the x-ray film of the abdomen may reveal findings typical of such lesions as congenital atresia or meconium ileus, or the appearance following a barium enema may justify a specific diagnosis such as volvulus, intussusception or diverticulitis. In a great many other patients, however, little or no preoperative evidence will be obtained from any source to indicate the mechanism or cause of the obstruction. This is particularly apt to be the case when the interference is in the small intestine.

Obstruction must be distinguished from many other disorders which cause abdominal

* The Richter type of femoral hernia is one of the few exceptions to this rule.

pain and vomiting. If the pain is of a cramping or colicky nature and is associated with inability to pass gas, there must immediately be suspicion of obstruction. The absence of the constitutional and abdominal signs of acute inflammation permits differentiation from such diseases as acute appendicitis, acute cholecystitis and peritonitis. In simple obstruction there is neither fever nor leukocytosis. Similarly, there is no definite tenderness,* either localized or general, and abdominal rigidity is absent. The sounds of increased peristaltic activity which are typical of mechanical obstruction, moreover, are rarely heard in association with the abdominal inflammations. Inflammation is usually accompanied instead by a reflex inhibition of intestinal motility, or ileus.

Diagnosis becomes more difficult if strangulation has ensued, since the signs of a local inflammatory lesion then begin to make their appearance and to become superimposed upon the symptoms of simple obstruction. Differentiation must be based upon the history and upon the other signs and symptoms of intestinal obstruction. Furthermore, when a sudden strangulation leads to hemorrhage or to shock, it may be confused with other conditions responsible for abdominal hemorrhages and with conditions such as perforated peptic ulcer which produce a temporary shock state on a neurogenic basis.

A particular problem in diagnosis arises in differentiating intestinal obstruction from other abdominal colics. Renal or ureteral colic and biliary colic are usually recognized easily because of the characteristic location and radiation of the pain. Such syndromes as lead colic and the abdominal crises of tabes dorsalis, sickle cell anemia and porphyria are rare but must be kept in mind along with the visceral neuropathy associated with diabetes. The more frequent difficulty concerns differentiation of mechanical obstruction from the intestinal colic of acute enteritis or gastroenteritis resulting from poisoning, infection or dietary indiscretion. The history is of great help in recognizing enteritis of this sort in that it may reveal ingestion of a possible poison or of an injudicious combination of foods. A story of previous food allergy also may provide a clue. In food poisonings, moreover, other associates or members of the household usually have been similarly and simultaneously stricken. In any case, the advent of diarrhea will re-

* Point tenderness at the site of attachment of an adhesion to the parietal peritoneum is an exception occasionally noted.

lieve all suspicion that the cramping pain is the result of mechanical obstruction. A delay in the onset of diarrhea, however, might lead to premature laparotomy on the assumption that an obstruction is present.

The differentiation of mechanical intestinal obstruction from neurogenic obstruction, or *paralytic ileus*, may be a very difficult diagnosis, especially during the days immediately following an abdominal operation. Since a temporary inhibition of intestinal motility occurs regularly after major abdominal surgery and is aggravated and prolonged when there is any significant degree of peritonitis, a possible basis for protracted ileus is present after many operations. Inasmuch as mechanical obstruction also may develop during the postoperative period, one is concerned in differentiating the two conditions whenever distention with obstipation and vomiting appears after abdominal surgery. The most important point enabling such differentiation is the fact that in paralytic ileus the waves of forceful and violent peristalsis characteristic of mechanical obstruction are absent. Consequently, the patient does not complain of cramping or colicky pain and on auscultation there is no increase in the sounds of peristaltic activity. Instead, the abdomen is relatively silent. X-ray scout films, moreover, show that gaseous distention is generalized rather than limited to the intestinal loops proximal to any level. Perhaps most important of all is the x-ray visualization of gas in the rectum and pelvic colon. In fact, in many cases of ileus, distention of the entire large bowel is a prominent feature. In advanced peritonitis, for example, the colon loops may be enormously distended.

As the intestine recovers from a period of reflex inhibition or ileus, there may be transient "gas pains," particularly if the bowel has been distended. The irregularity of these cramps, and the fact that gas is soon passed per rectum, ordinarily prevent confusion with the colic of a mechanical obstruction. Occasionally, however, the patient actually does enter a state of mechanical obstruction as ileus is subsiding. After peritonitis, for example, obstruction from adhesions is not infrequent and at a certain period the patient may be suffering from a "combined obstruction," both paralytic and mechanical.

Treatment. During the past twenty-five years there has been a remarkable reduction in the over-all mortality rate in acute intestinal obstruction. A decrease from a former rate of over 40 per cent to a current rate of

Figure 99 Diagram of suction apparatus employed in the should always be made to have the end of the catheter reach so that suction may be exerted simultaneously on the stomach and on the duodenum. If the apparatus is great, a third bottle should be used as a collecting receptacle (Wangensteen and Paine JAMA, vol. 110)

perhaps 10 per cent has been cited recently. Although the discovery of antibiotics, the development of improved techniques in operative surgery and improvements of anesthesia have played parts in this reduction, certainly the chief factors responsible have been the use of decompressing devices for prevention and correction of intestinal distention and the more effective replacement therapy made possible by constantly increasing knowledge of fluid and electrolyte balance. Since in the vast majority of patients the obstructing mechanism can be released only by operation, treatment of intestinal obstruction remains primarily surgical. However, intestinal decompression and parenteral replacement therapy are vital

supportive measures, often essential both to preparation for operation and to the after-care.

Decompression of the small intestine is accomplished by continuous aspiration of content by way of a tube passed through the nose into the stomach or upper intestine. The method was introduced by Wangenstein (1931-32), using a tube which passed through the stomach into the duodenum whenever possible, and applying constant gentle suction through the tube by means of a simple water siphon apparatus such as that shown in Figure 99. Following demonstration of the value of this method, Miller and Abbott (1934) introduced a longer tube for decompression, the tube having a double lumen and carrying an inflatable balloon in its tip. Once the tip of the Miller-Abbott tube has passed from the stomach into the

duodenum, the balloon is inflated to serve as a bolus which peristalsis propels distally along the intestine. If the intubation is ideally successful, the tip of the tube eventually comes to lie just proximal to the point of obstruction so as to effect complete emptying of the proximal intestinal loops. Passage of the tube through the pylorus continues to be a time-consuming and trying problem in intestinal intubation.

In discussing decompression, it should be emphasized that prevention of distention is not nearly so difficult as is the relief of distention once it has become established. In patients in whom distention has not yet occurred, the institution of simple gastric suction by way of a Levin tube which stops short of the pylorus will serve to recover all air swallowed thereafter as well as any liquid content which is regurgitated from the duodenum, provided, of course, that the tube is kept open so that it can function. This suffices to prevent the development of distention. Once distention is present, however, gastric suction, since it fails to empty the tract distal to the pylorus, serves only to prevent augmentation of the existing distention. If the Levin tube can be passed through the pylorus, decompression from within the duodenum is somewhat more efficient. However, for satisfactory removal of the voluminous content from loops which are already distended, intubation to a point beyond the duodenojejunal flexure, where sharp angulation may be caused by the ligament of Treitz, is most effective. This requires the use of the long tubes such as the Miller-Abbott tube.

After twenty-four hours, one may find that only gastric intubation has been accomplished. This difficulty remains the chief hindrance to effective decompression therapy, while the delay incident to unsuccessful attempts to intubate the intestine may be a very dangerous delay when treating patients having intestinal obstruction. Whereas, laparotomy admittedly is more hazardous when performed in the presence of marked distention, that danger to the patient is not so great as is the danger arising from delay when strangulation is present or imminent.

Although intestinal decompression is primarily a method for combating distention, the history of its development has been colored by constant attempts to substitute decompression for surgical operation in the definitive treatment of obstruction. These attempts are easily understood in the light

of the clinical experience that, in a number of patients having early or incipient obstruction of certain types in the small intestine, decompression of itself actually does serve to release the obstructing mechanism so that an emergency surgical operation becomes unnecessary. Very naturally, experience with such cases has led to trials in substituting decompression for operation in treating other patients with obstruction and many studies have been made to determine the possibilities and define the limitations of such *non-operative management*. Unfortunately, however, too little heed is given to repeated warnings pointing out the great difficulty in selecting patients in whom it is safe to defer operation while a satisfactory trial of decompression therapy is being made. Lack of appreciation of this difficulty continues to lead to costly misuses of decompression as a tentative substitute for surgery. Unless the surgeon is highly critical, a false sense of security is fostered by the cessation of pain and vomiting which follows institution of decompression and by the temporary improvement in the patient's condition which is brought about by the concurrent administration of water and electrolytes. Often these beneficial effects are interpreted as indicating a relief of the obstruction when in reality they mean only a relief of certain of its symptoms. In many instances, consequently, surgery is postponed unduly until a subsequent deterioration in the patient's condition finally forces operation upon the surgeon at a time when greater hazards are faced than would have been the case with prompt surgery. In these patients, it is not unusual for the tardy laparotomy to reveal that an unrecognized strangulation has been present and that the delay which had been intended for the patient's benefit has actually been to his great harm. Thus, it is the unhappy paradox that intestinal decompression, a valuable form of supportive therapy, through misuse becomes responsible for many of the deaths which continue to occur.

Decompression of the large intestine can only occasionally be accomplished by means of a tube passed through the nose into the small intestine. As previously noted, the ileocolic sphincter often serves as an effective one-way valve to prevent all regurgitation from the cecum into the ileum. Consequently, acute distention of the colon demands immediate surgical decompression by open operation. However, the use of nasogastric suction as an adjunct measure still

serves a useful purpose, since by recovering swallowed air it prevents additional distention of the small intestine.

In all intestinal obstructions, fluid is lost from the normal body fluid spaces, whether it be by vomiting, by collection of fluid in the lumen of the obstructed bowel or by retention in edematous tissues. The prevention of water and electrolyte imbalances and the correction of depletions already existing are of immediate concern in the treatment of each patient. The extent of replacement needed and the time available for its achievement are influenced necessarily by varying factors. The *level of obstruction* influences replacement requirements. In obstructions located high in the small intestine, losses by vomiting usually have been copious, whereas in colon obstructions there may have been no vomiting at all. The *elapsed time since onset of obstruction* is another important consideration. When obstructions are seen very early, replacement needs are correspondingly less than at later stages. The *possible presence of strangulation* is particularly important. It sharply limits the delay which is justified in order to effect replacement.

In treating patients having *obstruction of the small intestine*, the basic problem is that of correcting the dehydration which has resulted from lack of intake coupled with a loss of intestinal secretions, i.e., a dehydration comprising deficits both of water and of salt. A quick examination of the urine with regard to color, volume and specific gravity provides a rough measure of the extent of the dehydration. Correction is accomplished by intravenous administration of an adequate quantity of water and of sodium chloride. In patients with early cases, in whom only moderate losses have taken place, the administration of 1 or 2 liters of isotonic saline often suffices and this can be accomplished during the preparation for surgery and while the operation is in progress. In patients with late cases, however, several times this volume may be needed and the administration of such quantity ordinarily requires some hours. Glucose is added to reduce the caloric deficit. Appearance of dilute urine which contains chloride ordinarily indicates that water balance has been restored. In the meanwhile, determination of the carbon dioxide combining power of the blood will have revealed the extent of acidosis or alkalosis. Potassium replacement, if needed, is deferred until the output

of urine is good and, in emergency cases, can often be postponed until the postoperative period.

Vitamins B and C are added to intravenous infusions as needed. When history or examination suggests malnutrition, attention is directed particularly to the treatment of avitaminosis.

During recent years there has been better appreciation of the need for adequate blood transfusions in the preoperative preparation of many patients having small bowel obstruction. Loss of whole blood into the lumen of strangulated intestine or loss of plasma through the wall of edematous bowel calls for replacement in patients in whom it appears likely that such loss has been substantial. Moreover, transfusion of whole blood or plasma does much to sustain those patients in whom preparation for operation has been hurried of necessity because of obvious or suspected strangulation.

Large bowel obstruction usually presents quite different problems in the correction of physiologic deficits than does obstruction of the small intestine. As noted before, vomiting is not a prominent feature in colon obstruction, therefore losses of water and electrolytes usually are not acute. In view of the commoner causes of obstruction of the large bowel, the typical patient is older and suffers from a chronic illness. For these reasons, the surgeon is chiefly concerned with replacing blood, protein and vitamins rather than with administering water and salt. When the patient is seen before complete obstruction has become established, time may be available for reasonably adequate correction of the malnutrition and anemia, operation being deferred to a later time. This also permits the preparation of the colon with antibiotics. If the patient is not seen until acute obstruction is present, however, time is not available for complete replacement therapy or for full antibiotic protection, since necrosis and perforation may result from any considerable delay. In preparing for an emergency operation in such cases, a chief concern lies in assuring an adequate output of urine. Furthermore, in lieu of time for better preparation, blood transfusion is used freely to sustain the patient during surgery. Of great importance, moreover, is the practice of limiting the surgical operation to simple palliative decompression of the distended colon. Fortunately, a great majority of large bowel obstructions are of a nature to permit post-

ponement of definitive treatment to a later date.

Digital examination of the rectum is an essential diagnostic step in all patients with suspected intestinal obstruction. Fecal impaction, rectal stricture and pelvic tumor are examples of conditions sometimes discovered which alter the entire plan of treatment.

The majority of patients having obstruction will have been given one or more enemas in the process of establishing a diagnosis. Any continued evacuation of gas and liquid means that obstruction is not complete. The use of the enema is not entirely devoid of danger, however, and at times it is overdone. After the colon has once been evacuated, the use of a rectal tube or a colon tube is often preferable to more enemas. Continued passage of gas or liquid through the tube indicates progress in relieving the obstruction. The colon tube is the more effective, but to introduce a tube beyond the rectum into the sigmoid it is usually necessary to guide it visually by proctoscope.

Aside from their general value as an adjunct in surgery, antibiotic substances are particularly valuable in the treatment of strangulating obstructions since they help to delay the onset of necrosis as well as to combat its ill effects. For parenteral administration, a combination of penicillin and streptomycin with one of the broad-spectrum antibiotics such as Aureomycin is used frequently. A very promising development is seen in recent reports, both experimental and clinical, indicating that intestinal antiseptics are effective when introduced directly into the bowel during an emergency operation. For example, it is reported that when time has not been available for preoperative preparation of the bowel, neomycin is of value if used in this manner.

Not infrequently, in certain types of obstruction complete relief will be effected, at least for the time being, during the process of preparing the patient for operation. Obviously, an emergency operation becomes unnecessary if normal passage of gas by rectum is restored as a result of instituting upper intestinal decompression or, as sometimes happens, during the course of evacuating the colon by enemas. However, the patient should be observed for any return of symptoms and diagnostic studies planned to determine the cause of the obstructive threat. Often, an underlying lesion will be discovered which necessitates operation at a subsequent date.

When confronted with a case of complete obstruction, the surgeon must first arrive at a conclusion relative to the likelihood of strangulation existing. If he concludes that strangulation is present or imminent, operative treatment is mandatory and he must proceed with a minimum of delay. In most situations, an hour or longer will be required to prepare the operating room and to induce anesthesia. During this time isotonic saline solution is given intravenously while emergency laboratory determinations are made, antibiotics administered and blood transfusion started. Supportive treatment is continued during and after operation. In the presence of recognized strangulation, greater delay is seldom justified. Within this short period, the correction of water and electrolyte depletion can hardly be complete and often will be very inadequate. Liberal use of blood transfusion helps to sustain the patient in the emergency.

Immediate surgery is also required when acute colon obstruction is accompanied by marked distention. Otherwise, since many colon obstructions are of the closed-loop type, delay is apt to result in necrosis and perforation. Tube-decompression of the small intestine must never be expected to relieve the greatly increased tension within a distended colon.

When, in the surgeon's opinion, the obstruction is of a simple or nonstrangulating variety, he must remain alert to the possibility that it may change in character and frequent reassessment with respect to the possible presence of strangulation is essential. Furthermore, since it is notoriously difficult in some cases to recognize the advent of strangulation, he will be wise to avoid procrastination by setting in his own mind definite time limits for the preparation of the patient. This is particularly important when, in patients with distention, decompression therapy is being given a trial, for it will mask many of the symptoms of obstruction. Some advise immediate operation if the obstruction has not been relieved within a six-hour period, since that length of time will ordinarily suffice for minimal parenteral replacement.

Patients having early simple obstruction require the least in replacement therapy. Since distention is not yet severe, they are ideal for immediate operative relief and, under modern conditions, the surgical risk is not great. For these reasons, there is a good basis for recommending prompt surgery in all patients with early obstructions.

Although this will mean that a few patients will be operated upon unnecessarily, the risk in these few will be slight indeed. In the other patients, the danger of overlooking occult strangulation will be avoided. The over-all risk will be less than when such patients are treated first by a lengthy trial of decompression in the hope of releasing the obstruction without operation.

Early postoperative obstructions must be considered separately, since in such patients it may be impossible to observe the time limitations which are recommended for obstructions in general. After major abdominal surgery, a period of reflex inhibition of intestinal motility may be expected for a day or two. If, at the end of this period, symptoms arise which suggest mechanical obstruction, considerable additional time may be required to determine whether obstruction actually exists. Instead, the patient may be suffering from a prolongation of the paralytic ileus or may only be experiencing gas pains coincident with recovery of the intestine from ileus. A period of twenty-four hours or more may be needed to arrive at a diagnosis, whereas developments during the subsequent hours may serve to reverse that decision. Inasmuch as inflammation and edema commonly play an important role in the early postoperative period, a number of these postoperative obstructions are relieved completely by decompression therapy. This fact and the widespread impression that there is very little risk of strangulation have resulted in overconfidence in dealing with such cases. However, an early postoperative obstruction is not necessarily due to fresh adhesions; it may be the result of old adhesions, of volvulus or of hernia through a postoperative defect. Strangulation does result in 10 per cent or more of early postoperative obstructions. Therefore, once obstruction is diagnosed in these patients, surgical exploration is in order unless relief by intubation is prompt and unequivocal.

Operative treatment of mechanical obstruction is aimed primarily at restoring the physiologic continuity of the bowel by releasing the intestine from the interference which is occluding its lumen. Since any one of many and varied mechanisms may produce obstruction, the surgical steps required to relieve the situation obviously will vary greatly from patient to patient. The surgeon is concerned also with preventing a recurrence of obstruction, and treatment includes, when practicable, the definitive care of any causative lesion which is found.

In some cases effective operative treatment is relatively simple. In patients with early obstruction by an adhesion band, for example, there may be little difficulty in locating the junction of the collapsed distal intestine and the dilated proximal loops and in severing the adhesion which is causing the constriction deformity or the angulation at that level. Sometimes there are multiple obstructive sites where release must be afforded. Again, attachments which are not yet causing obstruction may also need liberation on the basis that they provide potential sites for future obstruction. Throughout the operation, all surgical manipulation must be gentle in order to avoid creating additional raw areas and thus encouraging formation of more adhesions. Moreover, any areas which do become freshly denuded are recovered with peritoneum if possible, and the remnants of adhesive bands are not left dangling to invite reattachment. When the operation is performed carefully, most patients having obstruction by adhesions can be relieved permanently and future difficulties avoided. Similarly, relief is not particularly difficult in patients with early obstructions arising from many other causes such as volvulus, intussusception and strangulated hernia.

Marked distention always makes surgery difficult technically and this results in greater trauma and hazard to the patient. When it has been impossible or impracticable to obtain relief by preoperative intestinal intubation, the use of nasogastric suction is important in order to prevent any increase in the distention already present. When surgery must be performed in the presence of severe distention, moreover, many surgeons have adopted the practice of deflating the distended intestinal loops by *direct suction aspiration* before closing the abdomen. Various trocars have been designed for introduction through the bowel wall to accomplish this purpose. Due care is taken to prevent spill and contamination of the peritoneum. Such direct evacuation of the distended intestine at laparotomy sometimes makes it possible to locate and release obstructions which otherwise would be extremely difficult of access. In addition, the patient is left in a condition more favorable to recovery than if the abdominal wall were closed over greatly distended bowel. Enterostomy, a procedure which consists in introducing a catheter into a distended loop of intestine—the loop immediately proximal to the obstruction if possible—the

catheter out through the abdominal wall to drain the intestinal lumen, often is disappointing by failing to relieve the distention.

When the obstructing mechanism has also interfered with the circulation to the obstructed loop so that *strangulation* exists, surgical treatment may be greatly complicated. In patients with early cases of strangulating obstruction, the release of the obstructed intestine and its mesentery by unwinding the volvulus, severing the constricting ring at the neck of the hernia or reducing the intussusception may lead to immediate return of a good circulation. Although the affected loop frequently retains the evidence of its recent venous engorgement and appears "angry" for a time, when it resumes its normal mobile position in the peritoneal cavity and is covered with warm, moist gauze, a few minutes often suffice to demonstrate its viability. The loop assumes a reddish hue, pulsations are palpable at the mesenteric margin and gentle mechanical stimulation elicits contractions which traverse the segment in question. These are the ordinary signs of adequate circulation. In more advanced instances of strangulation the intestinal loop may be frankly gangrenous or may have a borderline appearance which makes the decision as to viability very difficult. Again, sometimes the loop as a whole is clearly viable, but there are dark, lusterless spots which do not share in the general satisfactory appearance. Various special tests have been devised to determine the adequacy of the circulation in doubtful instances, but the safest rule for the surgeon to follow is to resect the intestinal loop when he has any doubt regarding its viability. After resection the continuity of the bowel is ordinarily restored by end-to-end anastomosis of the remaining intestinal segments. Occasionally, in critical operative situations, the gangrenous intestinal loop is exteriorized by bringing it outside the abdomen and closing the abdominal wall beneath it. This shortens the operation since the necrotic segment of intestine can then be excised without further anesthesia and the remaining ends of intestine left protruding above the abdominal wall. Since external discharge of the content of the large bowel creates no insuperable problem, this form of management is entirely feasible when a segment of gangrenous colon has been excised, and it is practiced sometimes in treating late sigmoid volvulus. If the

gangrenous loop is one of small intestine, however, such *exteriorization* is reserved for desperate situations, because the copious discharge of small bowel content not only excoriates the skin but also is apt to create a critical problem in water and electrolyte replacement.

In obstructions of the small intestine it is usually practical and desirable to combine at one sitting the release of the obstruction and the definitive treatment of the causative lesion. While this is sometimes necessary in large bowel obstruction also, as has just been mentioned in connection with sigmoid volvulus, in the usual case of *colon obstruction* the reverse is true. Experience has demonstrated that when large bowel obstruction is the result of a chronic disease, such as carcinoma or diverticulitis, the ill effects of the obstructive episode are superimposed upon the debilitation resulting from the causative lesion to the extent that surgical interference is not well tolerated and "one-stage" or "primary" colon resection becomes unduly dangerous. Although these obstructions are not strangulating obstructions in the ordinary sense, they do present an emergency situation since the rapidly mounting intraluminal tension may result in necrosis and perforation of the distended large bowel. Intubation of the small intestine, as previously stated, cannot be expected to relieve colonic distention and by far the safest procedure for these patients is immediate surgery in the form of *palliative decompression* of the distended colon. This consists of forming an artificial vent in the large bowel at a point proximal to the obstructing lesion. When the obstruction is in the left colon, which is the common site, a loop of transverse colon is brought out upon the abdominal wall and a transverse colostomy formed. Cecostomy is necessary if the obstruction is situated proximal to the transverse colon, e.g., at the hepatic flexure. Either procedure can be completed in a manner to provide immediate decompression of the distended colon. The emergency situation having been relieved in this fashion, time becomes available for adequate restoration of the patient by replacement therapy and for preparation of the intestine with antibiotics. The definitive treatment of the causative lesion can then be conducted at a later date. Such a "two-stage" operation, in which resection of the diseased bowel is attempted only after a period of decompression by proximal colostomy, is much the safest form

Although this will mean that a few patients will be operated upon unnecessarily, the risk in these few will be slight indeed. In the other patients, the danger of overlooking occult strangulation will be avoided. The over-all risk will be less than when such patients are treated first by a lengthy trial of decompression in the hope of releasing the obstruction without operation.

Early postoperative obstructions must be considered separately, since in such patients it may be impossible to observe the time limitations which are recommended for obstructions in general. After major abdominal surgery, a period of reflex inhibition of intestinal motility may be expected for a day or two. If, at the end of this period, symptoms arise which suggest mechanical obstruction, considerable additional time may be required to determine whether obstruction actually exists. Instead, the patient may be suffering from a prolongation of the paralytic ileus or may only be experiencing gas pains coincident with recovery of the intestine from ileus. A period of twenty-four hours or more may be needed to arrive at a diagnosis, whereas developments during the subsequent hours may serve to reverse that decision. Inasmuch as inflammation and edema commonly play an important role in the early postoperative period, a number of these postoperative obstructions are relieved completely by decompression therapy. This fact and the widespread impression that there is very little risk of strangulation have resulted in overconfidence in dealing with such cases. However, an early postoperative obstruction is not necessarily due to fresh adhesions; it may be the result of old adhesions, of volvulus or of hernia through a postoperative defect. Strangulation does result in 10 per cent or more of early postoperative obstructions. Therefore, once obstruction is diagnosed in these patients, surgical exploration is in order unless relief by intubation is prompt and unequivocal.

Operative treatment of mechanical obstruction is aimed primarily at restoring the physiologic continuity of the bowel by releasing the intestine from the interference which is occluding its lumen. Since any one of many and varied mechanisms may produce obstruction, the surgical steps required to relieve the situation obviously will vary greatly from patient to patient. The surgeon is concerned also with preventing a recurrence of obstruction, and treatment includes, when practicable, the definitive care of any causative lesion which is found.

In some cases effective operative treatment is relatively simple. In patients with early obstruction by an adhesion band, for example, there may be little difficulty in locating the junction of the collapsed distal intestine and the dilated proximal loops and in severing the adhesion which is causing the constriction deformity or the angulation at that level. Sometimes there are multiple obstructive sites where release must be afforded. Again, attachments which are not yet causing obstruction may also need liberation on the basis that they provide potential sites for future obstruction. Throughout the operation, all surgical manipulation must be gentle in order to avoid creating additional raw areas and thus encouraging formation of more adhesions. Moreover, any areas which do become freshly denuded are recovered with peritoneum if possible, and the remnants of adhesive bands are not left dangling to invite reattachment. When the operation is performed carefully, most patients having obstruction by adhesions can be relieved permanently and future difficulties avoided. Similarly, relief is not particularly difficult in patients with early obstructions arising from many other causes such as volvulus, intussusception and strangulated hernia.

Marked distention always makes surgery difficult technically and this results in greater trauma and hazard to the patient. When it has been impossible or impracticable to obtain relief by preoperative intestinal intubation, the use of nasogastric suction is important in order to prevent any increase in the distention already present. When surgery must be performed in the presence of severe distention, moreover, many surgeons have adopted the practice of deflating the distended intestinal loops by direct suction aspiration before closing the abdomen. Various trocars have been designed for introduction through the bowel wall to accomplish this purpose. Due care is taken to prevent spill and contamination of the peritoneum. Such direct evacuation of the distended intestine at laparotomy sometimes makes it possible to locate and release obstructions which otherwise would be extremely difficult of access. In addition, the patient is left in a condition more favorable to recovery than if the abdominal wall were closed over greatly distended bowel. Enterostomy, a procedure which consists in introducing a catheter into a distended loop of intestine—the loop immediately proximal to the obstruction if possible—and the

portance from the standpoint of the abdominal surgeon are those cases of ileus resulting from varying degrees of irritation and inflammation of the peritoneum and those cases arising from other lesions which give a clinical picture readily confused with peritonitis. Among the latter group, the injuries resulting in fractures about the ribs and spine or in retroperitoneal hemorrhage should have special mention. By irritation of spinal nerves or nerve roots, such lesions very commonly give rise to abdominal pain and muscle spasm, as well as to ileus and vomiting, so that the clinical picture may be particularly difficult to differentiate from that of peritonitis resulting from a ruptured viscus.

A temporary state of ileus is to be expected after abdominal operations as a result of the exposure of peritoneal surfaces and the manipulation of the viscera. This is the commonest form of traumatic peritonitis. When the operation is such that one anticipates an ileus persisting more than twenty-four hours, continuous gastric suction by way of a Levin tube introduced at time of operation is of great value. It prevents significant distention from air swallowing and minimizes postoperative vomiting. The tube is removed, of course, when the return of effective peristalsis is indicated by resumption of normal bowel sounds and passage of gas by rectum. Since it is much easier to prevent distention in this manner than it is to relieve distention which already has become established, such prophylactic gastric suction proves particularly valuable if peritonitis or obstruction arises later in the postoperative period. In fact, the absence of distention constitutes a distinct advantage in the management of almost every postoperative complication.

The severe form of paralytic ileus which accompanies bacterial peritonitis is illustrated by the sequence of events in neglected appendicitis. In the early stage of appendicitis when inflammation is limited to the appendix, the patient is usually constipated and may complain of inability to pass gas. As inflammation spreads onto the serosal surface of the appendix and then to the adjacent parietal peritoneum, "peritoneal irritation" usually results in a "quiet" abdomen with pronounced obstipation. An exception may be seen, however, in patients in whom the appendix lies adjacent to the rectum, where contact irritation may give rise to rectal tenesmus or diarrhea. If localization fails, so that there is diffuse and spreading

peritonitis, complete ileus becomes established and is unrelenting for a time. In general peritonitis following appendiceal rupture, for example, the loss of bowel motility can be expected to persist unabated for four or five days. By the end of the second or third day, the distention has become marked unless there has been effective gastric suction. The added complication of acute gastric dilatation was once very common; now it is rarely seen in patients under treatment on surgical wards where some form of decompression is used routinely. Resumption of intestinal peristalsis at the end of the five-day period indicates usually that the patient has weathered the critical infection and probably will recover, although complications, such as localized abscess or mechanical obstruction from adhesions, may still interrupt convalescence.

The diagnosis of paralytic, or inhibition, ileus is based upon the lack of bowel sounds and the absence of cramping pains in a patient suffering from distention, vomiting and obstipation. When the situation is one of ordinary postoperative ileus, the condition is only temporary and mild cramps concurrent with the return of peristalsis soon are followed by the passage of gas. Occasionally such "gas pains" are severe, particularly in patients who have been permitted to distend themselves with swallowed air during the postoperative period, and in these patients the differentiation from mechanical obstruction may be more difficult. The roentgen ray film, however, shows that the gas has a general distribution and is visualized in the large as well as the small intestine.

The appearance of pronounced ileus always suggests the possibility that peritonitis is present. If peritonitis actually exists, one finds abdominal tenderness and rigidity, either localized or general depending upon the extent of the inflammation. Pain is present but is constant rather than intermittent or colicky. Fever, tachycardia and prostration are constitutional signs of infection, along with leukocytosis. When ileus results from an extra-abdominal infection such as pneumonia, these same systemic signs appear, but abdominal tenderness and muscle spasm are lacking. Not infrequently in obese and older individuals, however, the abdominal tenderness of appendicitis may be difficult to detect for a day or longer and the development of silent distention of the abdomen is always an indication for repeated abdominal examinations.

Treatment of paralytic, or inhibition, ileus

of management when carcinoma of the colon or sigmoid diverticulitis has resulted in intestinal obstruction.

NEUROGENIC OBSTRUCTION OR ILEUS

Intestinal obstruction may be the result of nervous interference with the normal propulsion of intestinal content, just as it may arise from mechanical obstruction of the bowel lumen. Normal passage down the intestinal tract is accomplished through physiologically coordinated waves of muscular contraction. These peristaltic waves are dependent upon the intrinsic nerve plexuses in the intestinal wall and neither vagotomy nor sympathectomy abolishes them. However, though peristalsis originates through these local bowel reflexes, it is readily influenced by the extrinsic nerves. The vagus, whose terminals connect with ganglion cells in Auerbach's plexus, serves in general to augment peristaltic movements and to increase the tone of the smooth muscle of the intestine. In man, however, the vagus is not constantly or tonically active in augmenting intestinal motility and interruption of the vagi, surprisingly, is less apt to lead to intestinal stasis than to a temporary state of hypermotility and diarrhea. Moreover, the participation of the vagal innervation in pathologic disturbances of peristaltic coordination and in production of spasm rings and other impediments to intestinal passage remains obscure and uncertain.

The inhibitory effect of the sympathetic innervation, in contrast, is evidenced clearly in various pathologic states. The sympathetic fibers to the intestine pass peripherally mainly in the lesser splanchnic nerves. They terminate in the lower part of the celiac ganglion and in the superior mesenteric ganglion. From these ganglia, inhibitory impulses are relayed to the bowel through postganglionic neurons which pass uninterrupted through the intrinsic plexuses of the bowel wall to end in direct relation to the smooth muscle cells. That there is a certain amount of tonic inhibitory activity by way of these fibers is witnessed by the observation that spinal anesthesia, which interrupts conduction in the thoracolumbar outflow of the sympathetic, usually serves to augment intestinal peristalsis. In many disease situations, moreover, reflex sympathetic inhibition of intestinal motility is sufficient to produce a state of pronounced stasis leading to distention and vomiting. The effects of such reflex ileus may be fully as serious as are the effects of the comparable stasis

and distention arising from actual mechanical obstruction.

Paralytic ileus is the term commonly used in referring to the impairment of intestinal peristalsis which is seen, for example, when the peritoneum is the seat of an inflammatory reaction. A similar derangement of intestinal motor function may accompany traumatic or infectious lesions which are extraperitoneal or even extra-abdominal. In addition, ileus sometimes appears in conjunction with a generalized toxic state such as uremia or it may be seen in connection with severe electrolyte imbalance, particularly when potassium is deficient. In the case of uremia and of hypopotassemia, possibly the intestinal musculature actually is parietic in the sense that its intrinsic ability to contract has been reduced temporarily. Furthermore, in the advanced stages of distention from any cause, the muscle of the bowel may be exhausted from fatigue and overstretching. An intestinal segment which has been deprived of its arterial blood supply soon passes into a state of paralysis from ischemia. With these exceptions, however, the underlying fault in ileus ordinarily is not paralysis of the intestinal muscle, but rather an excessive neurogenic interference by way of sympathetic inhibitory fibers. Therefore, the term *inhibition ileus* would usually be more appropriate.

A standard classification of the causes of ileus is given in Table II. Of particular im-

Table II Classification of Causes of Ileus

- I Intra-abdominal
 - A Peritoneal irritation
 - 1 Traumatic peritonitis (including operative trauma)
 - 2 Bacterial peritonitis
 - 3 Chemical peritonitis
 - B Vascular changes
 - 1 Strangulation
 - 2 Mesenteric thrombosis or embolism
 - 3 Prolonged simple obstruction
 - C Extraperitoneal irritation
 - 1 Hemorrhage
 - 2 Infection
 - 3 Renal lesions
 - 4 Trauma to retroperitoneal nerves
- II Extra-abdominal
 - A Toxic
 - 1 Pneumonia, empyema
 - 2 Uremia
 - 3 Systemic infection
 - B Metabolic
 - 1 Porphyria
 - C Neurogenic
 - 1 Spinal cord lesions
 - 2 Fractures of spine or ribs involving nerve roots
 - 3 Lead poisoning
 - 4 Fluoride poisoning

testine, the resulting obstruction actually represents a failure of propulsion due to ischemic paralysis of the muscle of the affected bowel. When arterial obliteration is slow and the affected segment is short, the collateral circulation may be sufficient to prevent actual gangrene, particularly with the help of antibiotics. Sudden and massive occlusions, however, usually result in extensive infarction of the intestine and this is followed by peritonitis and its sequelae.

Mesenteric occlusion is seldom diagnosed prior to operation unless one has reason to expect embolism or venous thrombosis in the patient in question. Although the prognosis always is poor, it is not hopeless if the patient's condition will permit immediate resection of the stretch of gangrenous intestine with re-establishment of the continuity of the remaining bowel by anastomosis. Survival of a number of patients has now been recorded and in some of these the entire midgut had been gangrenous, so that resection was necessary from a level a few inches distal to the duodenojejunal flexure down to the proximal transverse colon. Patients with such massive intestinal resection suffer from anorexia, cramps and very severe diarrhea after operation. They present critical problems in replacement therapy and nutrition for many months. Impairment in the absorption of fats remains particularly severe. However, the fact that some have survived disproves the former belief that removal of more than *three-fourths* of the small intestine necessarily results in a fatal nutritional disturbance.

SPECIFIC LESIONS CAUSING INTESTINAL OBSTRUCTION

Intestinal Obstruction in Infancy. When congenital malformations result in complete intestinal obstruction, symptoms appear during the first day or two of life. Operative relief must be prompt or the infant will not survive. Parenteral fluid administration should precede surgery and gastric suction should be instituted to prevent vomiting and pulmonary aspiration. Otherwise, chest complications are a frequent cause of death.

The congenital malformations causing intestinal obstruction in infants include atresia and stenosis of the small intestine or colon, imperforate anus, meconium ileus, malrotation or incomplete rotation of the midgut and duplications of the intestinal tract.

Intussusception. The term intussusception refers to the telescoping or invagination of a portion of the large intestine into a more

distal portion. The receiving sleeve is called the intussusciens and the entering portion, the intussusceptum. Obstruction always results. Not only is peristalsis interrupted, but also the mesentery of the advancing intussusception becomes progressively compressed so that this entering bowel segment becomes edematous, violently congested and finally necrotic. The commonest intussusception is that of the ileum into the cecum or of the ileum and cecum into ascending colon. Rarely the ileum telescopes into the ileum or the colon into the colon. Though the usual intussusception consists of three layers or cylinders, double and compound varieties are described consisting of five and even seven cylinders. Intussusception which is secondary to the drag of a pedunculated tumor occurs in adults, but only rarely. In infancy and early childhood, in contrast, intussusception which is "idiopathic," i.e., has no demonstrable cause, is so frequent as to classify it as one of the most important surgical emergencies. The experience that 75 per cent of these patients are less than one year of age and that the peak of incidence occurs in babies between the ages of four and ten months suggests that the change from milk to a more solid diet may have some connection with the occurrence of many of the cases.

The infant with intussusception usually is a chubby, well-nourished baby, more often male than female. It is suddenly noticed that he appears to be having recurring attacks of violent abdominal pain which he evidences by grunting, crying, drawing up his legs and perhaps holding his abdomen. After the seizure passes, the child appears playful and well until the next episode five or ten minutes later. Usually, vomiting is an early symptom. As obstruction progresses, the child becomes pale and listless, even severely shocked. After one or more normal stools, the bowel movements consist of red or brownish mixtures of blood and mucus. Sometimes bleeding is sufficient to produce hemorrhagic shock. Abdominal palpation reveals very little tenderness or spasm, but ordinarily a round or sausage-shaped mass or tumor is felt along the course of the right, transverse or descending colon, a tumor which stiffens with the painful seizures. At the same time, the right lower quadrant appears empty on palpation. On digital examination of the rectum, blood is usually found and occasionally the cervix-like tip of the advancing intussusceptum can be palpated per rectum.

is essentially prophylactic and palliative. By avoiding preoperative cathartics and purgatives, by examining immediately all patients complaining of abdominal pain so that diagnosis and operation will be prompt in appendicitis, by performing surgical operations as gently and as expeditiously as possible and by using gastric suction routinely after major abdominal surgery, one can accomplish a great deal in preventing unnecessary occurrence of ileus and in minimizing its extent when it does occur. Once ileus is established, operative surgery has little to offer aside from the procedures which may be indicated in treating the underlying cause of the ileus. Enterostomy is usually disappointing in that it collapses only one loop of the distended intestine. Furthermore, it has been the general experience that the inhibited bowel fails to respond to such stimulating drugs as Prostigmin. Attention should be concentrated primarily upon supportive therapy and upon the prevention of additional distention through decompression. Since in most instances the intestine is not actually paralyzed, a balloon-tipped tube can sometimes be passed down the bowel. Otherwise, gastric suction prevents additional distention from air-swallowing, provided attention is directed toward maintaining the patency of the Levin tube. Along with the effort to prevent any increase in distention, parenteral replacement therapy and the administration of antibiotics are combined with whatever treatment is proper for the primary lesion. An additional measure sometimes found useful is the interruption of sympathetic inhibition by splanchnic block or spinal anesthesia.

Spastic, or dynamic, ileus, a temporary obstruction caused by spasm in a segment of intestine, is only occasionally of surgical importance. Patients exhibiting such intestinal spasm are apt to be of an extremely nervous make-up and one desires to avoid laparotomy if it is at all possible. However, since the symptoms are those of mechanical obstruction and the patient often has had a previous operation, the situation is easily confused with obstruction caused by postoperative adhesions. Inasmuch as adhesions usually obstruct the small intestine, whereas spastic areas are more common in the colon, x-ray demonstration of distention of the colon often helps in diagnosis. Knowledge regarding findings at a previous operation is also of aid in determining whether surgery is necessary. Functional disorders of digestion associated with a spastic descending colon often present similar though milder symp-

toms. A test with atropine or some other antispasmodic drug is of aid in differentiating them.

VASCULAR OBSTRUCTION

The term *vascular obstruction* refers to the relatively infrequent obstructions caused by mesenteric vascular occlusion. The vascular accident may be either arterial or venous. Most commonly, the superior mesenteric vessels are involved. Embolism of the superior mesenteric artery may occur in patients having vegetations on the heart valves, or other forms of heart disease, particularly when accompanied by atrial fibrillation. Thrombosis of the artery as a result of atheromatous plaques or arteriosclerotic narrowing at its aortic origin is not unusual. Mesenteric venous occlusion most commonly is a thrombophlebitis secondary to abdominal sepsis (pyelephlebitis). It can also result from trauma or from portal stasis, especially in individuals suffering from some disease such as polycythemia which predisposes to intravascular clotting. In still other patients with venous thrombosis, no cause whatever is found.

During the past few years a number of cases of occlusive, necrotizing inflammatory disease of the smaller distal arteries of the superior mesenteric system have been observed during the postoperative period following surgical correction of coarctation of the aorta. Whether this occurrence is related to alterations in the circulatory dynamics following operation or to some other factor, clinically the cases present the problems of mesenteric thrombosis.

Although the development of mesenteric vascular occlusion sometimes is insidious, with surprisingly few symptoms for a number of days, in the typical case the onset is sudden and catastrophic. There is severe abdominal pain, either continuous or cramping, with profound shock and collapse when the occlusion is massive. Vomiting usually is copious, and occasionally the vomitus is bloody. Peristalsis is more often absent than exaggerated. The roentgenogram usually reveals the presence of fluid in the peritoneal cavity. Otherwise it may be interpreted as showing either mechanical obstruction or paralytic ileus. Characteristically, marked leukocytosis is an early finding, although tenderness and rigidity may not be pronounced until gangrene has occurred in the affected intestine.

Since mesenteric vascular occlusion amounts to a denial of circulation to the in-

ministering morphine. Gentle manual reduction (taxis) can often be attempted more intelligently by the patient himself, who is accustomed to reducing his own hernia. The possibility of *en bloc* reduction must be kept in mind. Unless nonoperative reduction is unmistakably successful, operation is required for reduction. If the patient has symptoms of obstruction or if the irreducible hernial contents are tender, tense and painful, the operative section of the constricting ring at the neck of the sac must be immediate. If, after operative reduction, the intestinal loop concerned does not regain its color sufficiently to be clearly viable, it must be resected. Anastomosis follows, usually end-to-end, and then the repair of the hernia.

Volvulus. Some degree of twisting or torsion is not unusual in obstruction due to abnormal fixation of a loop of small intestine at some point owing to the presence of an adhesion band. Such secondary volvulus is an added factor in occluding the intestinal lumen and is particularly dangerous because of its strangulating effect upon the vessels in the mesentery. In its purer or "primary" form, however, volvulus is most apt to arise when there is a lack of adequate mesenteric fixation. In congenital malrotation, for example, volvulus of the entire midgut of an infant may result from defective attachment of the mesentery of that portion of the bowel. In adults, volvulus of this type is more frequent in the colon than in the small intestine. The long sigmoid loop is by far the commonest site, the narrow base of its mesentery no doubt predisposing. When volvulus of an abnormally mobile cecum is encountered, it is usually found to be a twist upon the axis of the ascending colon. Volvulus of the broad-based transverse colon is exceedingly rare.

The symptoms, diagnosis and treatment of volvulus of the colon are discussed in the section of this chapter dealing with the colon.

Gallstone Ileus. This is the name given to mechanical obstruction of the intestine by a very large gallstone and is uncommon since cholecystectomy has become widely practiced. Usually the stone has ulcerated its way into the duodenum from the gallbladder, rarely from the common duct, and the ordinary site for its lodgment is in the terminal ileum, though occasionally it lodges elsewhere. Ulceration and spasm may occur at the site, as may volvulus of the distended proximal bowel. For these reasons, the obstruction is a very dangerous one, particu-

larly since the obstructive symptoms often have relented and recurred to the extent that the patient comes late to surgery. The possibility of gallstone ileus should be kept in mind when obstructive symptoms arise in female patients having a history of gallbladder disease. Operation should be prompt and the stone removed from the intestinal lumen with minimal contamination of the peritoneum.

Diverticulitis. Diverticulitis of the sigmoid colon is a common inflammatory disease sometimes difficult to differentiate from sigmoid carcinoma; in fact, although unrelated, the diseases sometimes coexist. Obstruction in diverticulitis is seldom a complete obstruction, so that surgery is performed most commonly as an elective procedure in patients having recurring partial obstructions and in whom barium enemas in the past have demonstrated diverticulitis. With each recurring threat of obstruction in diverticulitis, there is usually some degree of exacerbation of the inflammatory aspects of the disease so that tenderness in the left lower quadrant, "left-sided appendicitis," helps to differentiate it from sigmoid cancer. Occasionally, however, both the clinical evidence and that from the barium enema are borderline and confusing, so that exploratory operation is necessary. If diverticulitis is encountered under these circumstances, and the bowel has been properly prepared for surgery, a primary resection is feasible so long as there are no signs of acute inflammation. In the presence of marked inflammation, however, or in the event of acute obstruction from diverticulitis, it is much safer to limit emergency surgery to proximal decompressing colostomy, since resection of the unprepared bowel in the presence of inflammatory edema is fraught with many dangers.

Fecal Impaction. Very rarely, concretions formed within the intestine cause intestinal obstruction. The term *fecal impaction*, however, does not refer to actual obstruction but to a disagreeable distention of the rectum by a hard mass of inspissated feces which the patient is unable to pass. Often there is a complaint of rectal tenesmus with constant desire to stool, which attendants may misinterpret as diarrhea. The diagnosis is obvious on digital examination. The mass must be broken up and removed digitally with the help of irrigations of oil or of dilute hydrogen peroxide. When caring for elderly patients, especially when they are bedfast, one must guard against impaction

In the typical cases of intussusception the diagnosis can be made on the history and physical findings alone. When it is the rare ileocolic intussusception, x-ray films of the abdomen reveal obstructed loops of small intestine. In other doubtful cases, the findings on barium enema are very helpful if the intussusceptum has entered the colon. Obstruction of the barium column, a cupping of the head of the column, a thin barium coating over the tip of the intussusceptum and spiral-shaped or ringlike stripes of barium are reported.

Operative reduction of intussusception is not difficult in patients with early cases. Through a right abdominal incision, the head of the intussusceptum is located in the left abdomen and gently "milked" backward into the right colon and thence through the ileocecal valve. Traction upon the proximal end of the intussusceptum is best avoided. If the reduced bowel is viable, nothing more need be done. When irreducibility or gangrene necessitates resection, and anastomosis of the remaining ends of bowel does not seem feasible at the first operation, the gangrenous loop can be exteriorized upon the abdominal wall. After the wall is closed about the limbs, the gangrenous portion of the intestine is resected and the two limbs left as a double-barreled Mikulicz enterostomy stoma. The enterostomy opening is closed as soon as practicable to alleviate the critical problems in water and electrolyte loss.

It has been known for a long time that in a great many patients with early cases of ileocolic intussusception, reduction can be accomplished safely by low-pressure colonic inflation with fluids or air. There has been recent revival of this method, using a low-pressure barium enema under fluoroscopic control. However, surgical opinion still remains sharply divided as to the wisdom of attempting such nonoperative reduction routinely before resorting to a surgical operation. If one desires to use the method, the nonoperative reduction must be promptly and unequivocally successful and great care must be exercised to assure that there has been no significant delay if surgical reduction still proves necessary.

Obstruction by Adhesions, Bands or adhesions are a common cause of intestinal obstruction. Some peritoneal bands are congenital, but many result from earlier operations, chiefly upon the appendix and female pelvic organs. Obstructions occurring during convalescence from surgery, or from

peritonitis, usually are a result of adhesive attachments which are still soft, vascular and only partly organized. With decompression therapy, recovery often follows without operation. However, strangulation does ensue in 10 per cent or more of these patients and operative intervention is indicated unless relief is prompt under nonoperative management.

Obstructions which occur months or years after operation result from firm cicatricial bands stretching as bridges between two peritoneal surfaces. In some instances a knuckle of bowel becomes wedged into the window beneath the band, while in others a loop passes through sufficiently long to invite twisting or volvulus ending in strangulation. The majority of conditions giving rise to such adhesion bands are situated in the right iliac fossa or in the pelvis, although occasional obstructions due to attachment of a *Meckel's diverticulum* to the umbilicus are at a higher level on the right. A right paramedian incision is appropriate in exploring for such obstructions.

Strangulated Hernia. This is perhaps the commonest cause of acute intestinal obstruction. With the exception of rare internal and concealed hernias, the site and cause of the obstruction are quickly apparent so that there is no clearer indication for immediate surgery. Although the intestine can become devitalized within two hours after the onset of strangulation, ordinarily gangrene is unlikely if the hernial "ring" is divided within four to six hours. In strangulated inguinal and femoral hernias, the trapped loops are usually ileal, while in strangulated umbilical hernias involvement of jejunal loops is more common. Although strangulation may be considered to be the logical end to which all hernias tend, those having a narrow and rigid neck particularly invite its occurrence. Femoral hernia is more apt to become strangulated than is any other, on account of the rigidity of the anatomic structures about the neck of the femoral sac, and the most rapidly developing gangrene of all may be encountered in the Richter type of femoral hernia, in which only a small area of bowel wall is pinched tightly in the rigid hernial orifice.

In all patients having acute abdominal pain one must think of hernia and examine its usual sites of occurrence carefully. If an irreducible hernia is found, a trial of nonoperative reduction may be made, adjusting the patient's position so as to relax the anatomic structures concerned and ad-

THE LIVER AND BILIARY SYSTEM

Anatomy and Physiology of the Liver and Biliary System and Diseases of the Gallbladder and Bile Ducts

By FRANK GLENN, M.D.

FRANK GLENN was born in southern Illinois, attended Washington University and its medical school. Surgical training at the Peter Bent Brigham Hospital and The New York Hospital preceded his investigative interests in surgical problems of immediate importance to the care of the surgical patient. Successor to George Heuer, he has brought a midwestern background to the Lewis Atterbury Stimson Chair of Surgery at Cornell University and The New York Hospital.

The liver and biliary system are so intimately associated with digestion and the body metabolism that impairment of their function diminishes the efficiency of the total body economy. An understanding of these processes requires an accurate knowledge of the anatomy, physiology and pathology of these complete systems. Departures or variations from the normal range of structure and function are the basis for considerable

disability. Of course, Nature allows for some latitude in both of these, but beyond a certain degree of deviation from the normal, which we call the pathologic, signs and symptoms appear that experience has taught us are indicative of failing health.

The interruption of these changes is important to the patient, first in that the conditions they produce must be corrected to release him of his symptoms; second, because

of feces in the rectum by regular attention to the bowels and by periodic rectal examinations

rate—estimated to be near 10 cc. per hour—and save for that time when active digestion is going on it goes to the gallbladder. There it is concentrated by the absorption of water and some salts through the wall of the

gallbladder. Thus, the bile in the gallbladder may be concentrated five to ten times with a marked increase in the concentration of bile salts, pigment, calcium and cholesterol (Fig. 1B).

**LIVER, GALLBLADDER
AND EXTRAHEPATIC
BILIARY DUCTS —**

A

B

Figure 1. A, Gallbladder and extrahepatic ducts. Inset, Schematic detail of junction of cystic with common duct. B, Schematic diagram after Hans Elias portraying the liver as a spongelike structure of cells penetrated by communicating system of cavities or lacunae through which courses the blood from the portal tract to the central vein. These sinusoids are lined with the all-important Kupffer cells.

if they persist he may become more susceptible to additional disease processes, and, finally, the longer their duration the more resistant they are to interruption or reversal.

The early recognition and proper interpretation of the signs and symptoms of biliary tract disease are essential to efficient therapy. The surgeon who undertakes to treat these patients must clearly understand the objectives, principles and technical procedures involved and their associated hazards. Furthermore, the maximum success with the minimum risk will be provided the patient by the surgeon who is firmly grounded in the significance and frequency of anatomic abnormalities and the underlying pathologic processes of injuries and disease of the liver and biliary tract.

ANATOMY OF THE LIVER AND BILIARY SYSTEM

The liver, an essential organ of the body, may be considered as made up of four lobes—the right, left, caudate and quadrate. Each has a ductal system that receives tributaries from its functioning units and unites with those of the other lobes near the hilum to form the common hepatic duct (Fig 1). Closely associated in this area are the hepatic artery and portal vein which enter the liver.

Until recently it was commonly accepted that the functioning units of the liver were the lobules that make up the lobe. It was believed that each lobule consisted of polygonal cells arranged about the ramifications of the portal vein, while on the opposite side, or periphery, were the small branches of the hepatic artery, hepatic vein and bile canaliculi. The lobules were considered individual functioning units separated from each other by connective tissue. Now, chiefly because of the research of Hans Elias, the liver is looked upon as a spongelike structure of cells penetrated by a communicating system of cavities or lacunae. These contain the blood capillaries of the liver, the sinusoids. The endothelial lining is formed by the Kupffer cells. These are traversed by two mesenchymal tracts arranged about the vessels and bile ducts, one being the portal tract, the other the central vein.

In the liver cell, many complex functions take place that have far-reaching effects upon the body as a whole. Blood, both portal and systemic, arterial and venous, provides the materials in large quantity. The bile produced and secreted into the canaliculi is but a small part of these complicated processes.

The common hepatic duct is formed by the ductal systems from the lobes as they emerge from the liver in the hilum as the right and left hepatic ducts; about 4 cm. distal from the junction of the right and left hepatic duct the cystic duct unites to form the common bile duct. The common bile duct (ductus choledochus) measures about 8 cm. from the cystic duct to where it empties into the duodenum. It extends through the edge of the lesser omentum, passes behind the upper margin of the duodenum and through a portion of the head of the pancreas to enter the duodenal wall obliquely and empty into the intestine through the ampulla of Vater. In almost 70 per cent of individuals the main pancreatic duct empties into the common bile duct within 2 cm. of the ampulla of Vater. In the remainder, the pancreatic duct may open directly into the duodenum. In addition to the blood from the portal vein, which lies medial and posterior to the common duct, the liver also receives systemic arterial blood from the hepatic artery which comes through the edge of the lesser omentum slightly to the left. The cystic artery which supplies the gallbladder usually passes posterior to the common duct and between the cystic duct and liver to enter the gallbladder wall. If one places the index finger in the foramen of Winslow and compresses the structures between it and the thumb, the flow within the cystic and hepatic arteries will be readily occluded. This is sometimes desirable when there is bleeding from the cystic artery in the course of surgical procedures in this area.

The gallbladder is a pear-shaped structure attached to the inferior surface of the liver at the junction of the right and quadrate lobes. Its extrahepatic portion is covered with peritoneum, communicating with the common duct by the cystic duct; it receives bile as it is produced in the liver, concentrates it and later returns it through the same channel to the common duct and into the duodenum.

PHYSIOLOGY OF THE GALLBLADDER

The functions of the extrahepatic biliary system include the transportation, concentration and storage of bile after its production in the liver and before its delivery into the duodenum as needed. Bile as it comes from the liver is made up of 97 per cent water, 1 to 2 per cent bile salts and about 1 per cent of pigment, cholesterol and fatty acids (Table 1). The bile is produced at a constant

Figure 2 Biliary fistula, bile output in seventy-six days, demonstrating considerable fluctuation from day to day, but averaging slightly over 900 cc for twenty-four hours.

derived from the breakdown of hemoglobin by the Kupffer cells as well as bilirubin. By phagocytic activity they also remove bacteria, pigment and cellular elements from the blood.

Formation of Fibrinogen and Prothrombin. Prothrombin formation in the liver is governed by vitamin K. This substance in association with fibrinogen is essential for the clotting of blood. Fibrinogen is believed to be produced in the liver.

Red Blood Cell Production. Red blood cells are produced in the liver during embryonic life. Sometimes, with the destruction of the bone marrow in later life, red cells may again be formed in the liver.

Detoxification. The function of detoxifying injurious substances brought to the liver by the portal circulation from the intestinal tract is not well understood. It is probable that some of the injurious substances are destroyed and others are conjugated with other substances to render them nontoxic, while still others are excreted as are some bacteria.

Vasodepressor Substance Elaboration. In the presence of hypoxia or anoxia, the liver elaborates a vasodepressor substance (VDM) that has been studied by Shorr. Since the production of this material may be inhibited by the hypoxia caused by anesthesia and because toxic anesthetic agents

may cause liver necrosis, this function of the liver is of great concern to the surgeon.

CONGENITAL ANOMALIES OF THE GALLBLADDER AND EXTRAHEPATIC DUCTS

The gallbladder may be, but is rarely, absent. It may vary greatly in size, shape and its attachment to the liver. An occasional gallbladder may be completely intrahepatic, it may be deeply embedded in liver substance or loosely attached by a mesentery. Bile ducts from the liver may enter the gallbladder directly or indirectly through the cystic duct.

Congenital anomalies of the extrahepatic ducts and the arterial system of this region are numerous and great emphasis has come to be placed upon them. The anatomic relationships vary so much that the surgeon must always be alert not to mistake structures. The cystic duct may be so short that it can hardly be identified; it may be very long and extend parallel to the common duct for several centimeters; it may enter the common duct from any point in its circumference. There may be duplication of a segment or of the entire common duct. There may be accessory ducts from the liver to the gallbladder, in addition to the cystic duct and the common duct. There may be congenital cystic dilatation in any of these,

Table 1. The Composition of Bile

	LIVER BILE	GALLBLADDER BILE
Specific gravity	1 009-1 013	1 026-1 032
pH	7 1-8 5	5 5-7 7
Total solids (%)	1-3 5	4-17
Mucin (%)	0 1-0 9	1-4
Bile acids (%)	0 2-2	1.5-10
Bile pigment (%)	0 05-0 17	0 2-1 5
Total lipid (%)	0 1-0 5	1 8-4 7
Cholesterol (%)	0 05-0 17	0 2-0 9
Phosphate (%)	0 05-0 08	0 2-0 5
Inorganic (%)	0 2-0 9	0 5-1 1
Total base (mEq /liter)	150-180	
Chloride (mEq /liter)	75-110	15-30
Calcium (mg %)	4-9	10-14
Iron (mg %)	0 03-7	

The flow of the bile from the gallbladder is believed to be stimulated by a hormone, cholecystokinin, which is secreted into the blood stream when acid chyme comes into contact with the duodenal and jejunal mucosa. Cholecystokinin causes an increase in the tone of the gallbladder, increasing its intraluminal pressure from 300 mm of water to nearly 375 mm and returning the bile to the common duct. At the same time that the gallbladder contracts to return the bile to the common duct through the cystic duct, the sphincter of Oddi relaxes so that the bile flows through the ampulla of Vater into the duodenum without an increase in pressure within the common bile duct. When ingested, certain foods such as fats, egg yolk and those high in cholesterol act as a strong stimulus for the gallbladder to empty.

Loss of the gallbladder is compensated for by the dilatation of the extrahepatic ductal system. While it is probable that the digestive process is somewhat reduced in efficiency by the more constant flow of the bile into the duodenum after cholecystectomy, no untoward symptoms appear. Many animals do not have gallbladders (e.g., horses, rats).

The concentrating function of the gallbladder is invoked in preparation for Graham-Cole cholecystography, a test in which an iodine-containing compound administered to the patient and excreted in the bile becomes sufficiently concentrated in the gallbladder to be visualized on the x-ray film and enables one to outline gallstones and estimate the degree of normal function of the intact gallbladder if the dye enters it. If the gallbladder does not receive the dye, then it may be assumed that there is obstruction of the cystic duct or the ampulla of the gallbladder.

PHYSIOLOGY OF THE LIVER

The liver has many functions that are known and we believe there are many more to be discovered. It is essential to life. Many have demonstrated that death preceded by liver failure follows within ten to twelve days after hepatectomy. The liver also has a great regenerative power. In the experimental animal as much as 70 per cent of the liver can be removed with apparent complete regeneration taking place in a few weeks. The same degree of regeneration has also been observed to take place in man.

Of the many known functions of the liver, the following are of the greatest importance:

Carbohydrate Metabolism. The liver is one of the major body reservoirs for glycogen and consequently plays an important role in the regulation of the quantity of sugar in the blood. Glucose and other sugars are converted and stored in the liver as glycogen. Adequate glycogen aids the liver in resisting the injurious effects of many toxic and noxious substances. Protein and a part of the fat can also be used by the liver to make glycogen and are therefore important in carbohydrate metabolism.

Protein Metabolism. Protein metabolism including deamination of the amino acids with the formation of urea and the destruction of uric acid, as well as the storage of proteins takes place in the liver. Here many of the serum proteins are formed.

Fat Metabolism. Fat is received from the circulation and may be stored in limited amounts in the liver. It may be broken down with the formation of ketone bodies. In case of deficiency the liver may form fat from other substances.

Vitamin Metabolism. Prothrombin, which is of such great importance in the clotting mechanism, is formed in the liver. Vitamin K is essential to its formation. Vitamin A is formed from carotene in the liver and vitamin B is stored and utilized in the liver.

Formation of Bile. Bilirubin, one of the important constituents of bile, is manufactured by the liver from the hemoglobin of broken-down red cells. The liver also forms bile salts and acids. These with cholesterol, a fatlike substance which is actually a higher alcohol, are also excreted by the liver and make up the other important constituents of bile. Bile is secreted continuously during a twenty-four-hour period at about the rate of 30 to 50 cc. per hour for a total daily production of 800 to 1200 cc. (Fig. 2).

Gamma globulin and immune bodies are

Figure 2. Biliary fistula, bile output in seventy-six days, demonstrating considerable fluctuation from day to day, but averaging slightly over 900 cc for twenty-four hours

derived from the breakdown of hemoglobin by the Kupffer cells as well as bilirubin. By phagocytic activity they also remove bacteria, pigment and cellular elements from the blood.

Formation of Fibrinogen and Prothrombin. Prothrombin formation in the liver is governed by vitamin K. This substance in association with fibrinogen is essential for the clotting of blood. Fibrinogen is believed to be produced in the liver.

Red Blood Cell Production. Red blood cells are produced in the liver during embryonic life. Sometimes, with the destruction of the bone marrow in later life, red cells may again be formed in the liver.

Detoxification. The function of detoxifying injurious substances brought to the liver by the portal circulation from the intestinal tract is not well understood. It is probable that some of the injurious substances are destroyed and others are conjugated with other substances to render them nontoxic, while still others are excreted as are some bacteria.

Vasodepressor Substance Elaboration. In the presence of hypoxia or anoxia, the liver elaborates a vasodepressor substance (VDM) that has been studied by Shorr. Since the production of this material may be initiated by the hypoxia caused by anesthesia and because toxic anesthetic agents

may cause liver necrosis, this function of the liver is of great concern to the surgeon.

CONGENITAL ANOMALIES OF THE GALLBLADDER AND EXTRAHEPATIC DUCTS

The gallbladder may be, but is rarely, absent. It may vary greatly in size, shape and its attachment to the liver. An occasional gallbladder may be completely intrahepatic, it may be deeply embedded in liver substance or loosely attached by a mesentery. Bile ducts from the liver may enter the gallbladder directly or indirectly through the cystic duct.

Congenital anomalies of the extrahepatic ducts and the arterial system of this region are numerous and great emphasis has come to be placed upon them. The anatomic relationships vary so much that the surgeon must always be alert not to mistake structures. The cystic duct may be so short that it can hardly be identified; it may be very long and extend parallel to the common duct for several centimeters, it may enter the common duct from any point in its circumference. There may be duplication of a segment or of the entire common duct. There may be accessory ducts from the liver to the gallbladder, in addition to the cystic duct and the common duct. There may be congenital cystic dilatation in any of these,

although the common duct is the more frequent site for such to occur. Defects in continuity and atresia of the bile ducts are not infrequent and are to be considered in young infants with persistent jaundice and inspissated bile and mucus.

CONGENITAL ATRESIA OF THE BILE DUCT

Complete obliteration of the lumen of any segment of the biliary tract is labeled biliary atresia. This may involve a part or all of the gallbladder, the cystic, common or intrahepatic ducts. Dependent upon the location and extent, some of these abnormalities may be corrected surgically. Gross reports that in 146 patients with this condition, twenty-seven or 18 per cent were subjected to a remedial anastomotic procedure.

If the atresia involves the common duct or one of its major hepatic tributaries, obstructive jaundice results. Since jaundice in the newborn is relatively frequent, it becomes indicative of atresia only if it persists and/or increases after two to three weeks. If the obstruction is in the extrahepatic common duct, the stools from birth will be acholic. Thus as weeks elapse, the jaundice and the pigmentation of the tissues become more marked. The circulating pigment in the blood stream may impart some color to the feces, but this is minimal. Intermittent jaundice and intermittent normal-colored stools rule out the likelihood of atresia.

The obstructive jaundice is accompanied by progressive changes in the liver. It enlarges, becomes nodular, firm and a deep green color. The end result is portal cirrhosis with all gradations of liver cellular degeneration, together with considerable hepatic cell regeneration. As a result of this progressive extensive liver damage over a matter of months, a bleeding tendency develops because of a lowered prothrombin level. If the condition is uncorrected, the infant with biliary atresia, while maintaining a fair state of nutrition, develops slowly physically and mentally and is distinctly lethargic. As the liver enlarges, splenomegaly and ascites appear and death usually occurs within the first two to three years of life as a result of liver deficiency.

The surgical treatment, when feasible, consists in establishing a satisfactory pathway for the bile to reach the intestine. When feasible, the most promising procedure consists in the excision of the atretic portion of the ductal system followed by establishment of continuity by an end-to-end anastomosis. If the atresia is in the common

duct distal to the cystic duct, then one may anastomose the gallbladder to the intestine to provide a pathway for the bile.

Over a twenty-year period we have encountered twenty-seven patients with congenital atresia of the ductal system at The New York Hospital-Cornell Medical Center. The diagnosis was confirmed at operation in seventeen, at necropsy in three, and at operation and autopsy in seven. The diagnosis was established between the ages of four days and one year. Twenty-four of the patients were operated on, but in only ten cases was some form of surgical correction feasible. Although nine of these lived for from two months to nine and three-fourths years, only two are known to have a satisfactory result. Eight patients unsuitable for surgical correction lived for from fourteen months to six years. Because the usual microscopic sections of the liver in these patients with congenital atresia show the parenchyma to be composed of hepatic cells, separated by broad bands of fibrous tissue containing proliferating bile ducts, it is not likely that the results of surgical procedures will improve.

TRAUMA

An increasing number of automobiles traveling at greater speeds than ever before accounts for the more frequent occurrence of highway accidents which result in serious injuries. Among the victims of such accidents are persons who sustain major trauma to the abdomen without a penetrating or open wound. A very high mortality rate is associated with injuries to the liver and biliary system in this type of trauma.

Nonpenetrating trauma which produces rupture of a viscus may cause little evidence of external injury. When rapidly moving automobiles suddenly collide, occupants of the car may sustain injuries to the viscera with little evidence of external trauma, particularly if they are fully clothed. The liver, under these circumstances, is frequently injured. Its location and attachment which prevent its escape from the forces involved, as well as its weight, consistency and shape, are factors contributing to the vulnerability of the liver.

Liver injury with hemorrhage and/or escape of bile is accompanied with an increase in pulse rate. The rapidity with which the pulse rate increases is often an index to the magnitude of the injury. An increasing pulse rate is indicative of an approaching fall of blood pressure and shock.

A degree of liver injury sufficient to produce shock usually will result in considerable hemorrhage and some escape of bile. However, it may be that injury to other parts of the body caused the shock and the liver injury may have been sufficient to have resulted immediately in blood loss or bile escape. Thus the shock may be temporary and by the time the patient arrives at a hospital he may have a stable blood pressure and pulse. In either of these two situations, hemorrhage may again begin and continue. Thus, together with the escape of bile into the peritoneal cavity, can result in rapidly progressive shock which within a short time is irreversible. In addition, this group of patients has usually sustained partial to complete interruption of the many normal physiologic functions of the liver. These are complex not only individually but in relation to the total body economy.

accident, the patient should be prepared and operated upon with as little delay as is compatible with anticipating the common exigencies. Delay increases the risk that the injury entails as well as the risk of the operative procedure.

There are all manner and variations of the extent and nature of these injuries. In general it may be said that free and partially detached fragments should be removed. In cases in which the injury is limited to the left lobe, extensive lobectomy may be the procedure of choice. Rupture and superficial lacerations may be closed with any one of the various suture methods. Where there is complete rupture through capsule and parenchyma after removal of free fragments of liver, massive sutures that seek to control hemorrhage and occlude the biliary ducts may be effectual. All traumatic wounds of the liver and biliary system should be provided with drainage which will permit the escape of bile through the abdominal wall to the exterior.

A gallbladder which is lacerated or detached from the liver bed should be excised. Lacerations of the extrahepatic ductal system should be meticulously repaired with fine interrupted silk sutures and proximal decompression instituted by means of a rubber T tube.

Following operation for trauma to the liver, all patients will have some degree of peritonitis due to bile, hemorrhage or infection. Their treatment should include all

measures commonly employed, including gastrointestinal decompression, maintenance of proper water and electrolyte requirements and chemotherapy.

Based on a review of the literature and our observations, we estimate that of those persons in automobile accidents who, as a result of nonpenetrating trauma, sustain injury to the liver and biliary system which is not treated surgically, one-third die at the site of the accident, one-third die within six hours and one-third survive.

GALLSTONES

Incidence. It may be safely estimated that 10 per cent of the entire population of the United States and 20 per cent of those over forty years of age have gallstones.

If one looks at the incidence of the disease over the entire life span, it is one that increases the longer life continues. In infants and young children, gallstones are so rare that they are seldom given serious thought in a differential diagnosis. They have been reported in the newborn at autopsy. Before the age of puberty their occurrence is usually associated with some type of blood dyscrasia such as hemolytic jaundice. During adolescence, disturbances of metabolism may be present and stones may develop. In the female, pregnancy is accompanied or followed by the appearance of gallstones with sufficient frequency to have established it as one of the most frequent diseases associated with gestation. Between the ages of thirty-five and fifty-five years, men, and women who have not been pregnant, show an equally high incidence of symptoms of gallstones far beyond those of the younger age group. Studies of routine autopsy material have confirmed the clinical impression that there is a precipitous increase of gallstone incidence in individuals of the thirty-five- to fifty-five-year group. Thereafter, although the incidence does increase, it is more gradual. It has been estimated that one out of each three individuals who reach the age of seventy-five years will have gallstones. This should make us think about the changes in the physiologic functions of the body as it grows older. Indeed, the appearance of stones in adult life and their increased incidence with increased age are strongly suggestive that defects from the normal physiologic functions are involved.

It is to be observed in the analysis of various reported series of patients with gallstones that if the number of women who have been pregnant is subtracted from the

although the common duct is the more frequent site for such to occur. Defects in continuity and atresia of the bile ducts are not infrequent and are to be considered in young infants with persistent jaundice and inspissated bile and mucus.

CONGENITAL ATRESIA OF THE BILE DUCT

Complete obliteration of the lumen of any segment of the biliary tract is labeled biliary atresia. This may involve a part or all of the gallbladder, the cystic, common or intrahepatic ducts. Dependent upon the location and extent, some of these abnormalities may be corrected surgically. Gross reports that in 146 patients with this condition, twenty-seven or 18 per cent were subjected to a remedial anastomotic procedure.

If the atresia involves the common duct or one of its major hepatic tributaries, obstructive jaundice results. Since jaundice in the newborn is relatively frequent, it becomes indicative of atresia only if it persists and/or increases after two to three weeks. If the obstruction is in the extrahepatic common duct, the stools from birth will be acholic. Thus as weeks elapse, the jaundice and the pigmentation of the tissues become more marked. The circulating pigment in the blood stream may impart some color to the feces, but this is minimal. Intermittent jaundice and intermittent normal-colored stools rule out the likelihood of atresia.

The obstructive jaundice is accompanied by progressive changes in the liver. It enlarges, becomes nodular, firm and a deep green color. The end result is portal cirrhosis with all gradations of liver cellular degeneration, together with considerable hepatic cell regeneration. As a result of this progressive extensive liver damage over a matter of months, a bleeding tendency develops because of a lowered prothrombin level. If the condition is uncorrected, the infant with biliary atresia, while maintaining a fair state of nutrition, develops slowly physically and mentally and is distinctly lethargic. As the liver enlarges, splenomegaly and ascites appear and death usually occurs within the first two to three years of life as a result of liver deficiency.

The surgical treatment, when feasible, consists in establishing a satisfactory pathway for the bile to reach the intestine. When feasible, the most promising procedure consists in the excision of the atretic portion of the ductal system followed by establishment of continuity by an end-to-end anastomosis. If the atresia is in the common

duct distal to the cystic duct, then one may anastomose the gallbladder to the intestine to provide a pathway for the bile.

Over a twenty-year period we have encountered twenty-seven patients with congenital atresia of the ductal system at The New York Hospital-Cornell Medical Center. The liver, under these circumstances, is frequently injured. Its location and attachment which prevent its escape from the forces involved, as well as its weight, consistency and shape, are factors contributing to the vulnerability of the liver.

Liver injury with hemorrhage and/or escape of bile is accompanied with an increase in pulse rate. The rapidity with which the pulse rate increases is often an index to the magnitude of the injury. An increasing pulse rate is indicative of an approaching fall of blood pressure and shock.

volves the cells adjacent to the smallest bile canaliculi. The reparative process that takes place in the liver is remarkable, but the end result of repeated episodes of this nature is the *biliary cirrhosis* not infrequently seen in the old patient (over sixty-five years of age) with a small contracted gallbladder containing stones and with stones in the common duct. Morphologic changes are evidence of advanced liver changes, hepatic function, however, may be markedly impaired before these are evident.

Finally, malignant disease—carcinoma of the biliary tract—follows in the wake of gallstone formation. The incidence of stones associated with carcinoma is over 50 per cent, regardless of site, and ranges from 50 to 90 per cent in reported series of patients with carcinoma of the gallbladder.

Gallstone Formation. Gallstones are concretions that form anywhere in the biliary tract, although it is believed that most of them form in the gallbladder. They vary greatly in content, size and shape.

They may be of almost pure cholesterol, inorganic calcium salts, calcium in combination with bilirubin, or any combination of a mixture of these substances and they often include cellular debris and bacteria. The cholesterol stones may occur singly, tend to be rounded, of yellow-white color and consist of radiating crystals. They are usually fairly large. Bilirubin calcium stones are black in color and assume various shapes, being irregular, faceted or rounded. They vary greatly in size from that of sandlike particles to calculi a centimeter or more in diameter. They are of a homogeneous structure, either crystalline like the cholesterol stones or laminated like the mixed calculi. They are encountered in patients with hemolytic disease. The most common stones are the mixed type. These represent a combination of the two previously described and may contain cholesterol, bilirubin calcium, cellular debris and bacteria. They also vary greatly in size, shape and consistency. They are usually laminated and have a central nucleus that is soft with superimposed concentric layers of varying amounts of cholesterol, bilirubin and calcium. Each concretion is considered to have an individual nucleus of a precipitate, cellular debris, bacteria or other foreign body material.

The mechanism whereby stones are formed in the gallbladder and biliary ductal system is not completely understood. Much study has been devoted to this problem. Many isolated and easily comprehended

facts have been revealed. Many more associated and complex fragments of information difficult to interpret have been brought forth by numerous investigators. No single theory provides an adequate explanation for all gallstone formation. Perhaps the most satisfactory explanation is that stone formation is the result of general variations from the normal functioning of the liver and biliary system. These may be the result of disturbances in metabolism, of infection or of stasis or obstruction.

Bile metabolism. There are a group of diseases—congenital hemolytic anemia, sickle cell anemia and similar disorders—in which hemolysis of red cells produces an increase in the bilirubin excreted in the bile. In patients with such conditions the incidence of gallstones is high. The stones consist chiefly of bilirubin and are believed to form by crystallization as the result of hyperconcentration. The mechanism in disturbances of cholesterol metabolism does not appear as evident. However, a few facts are known; for example, bile acids keep the cholesterol of the bile in solution. In normal bile the ratio is about 20:1. If the concentration of the bile within the gallbladder reduces this to 13:1, cholesterol precipitates out in crystalline form and may be the nucleus of a stone.

Stasis and infection may play an important role in this change in concentration. Much investigation and study have failed to demonstrate a direct and constant relationship between the cholesterol content of bile and that of the blood serum. In pregnancy, however, it is common for both to be elevated, but all pregnant women do not develop gallstones. While some defect in cholesterol metabolism probably accounts for many instances of gallstone formation, we cannot be specific just where in the long and intricate chemical process it occurs.

Infection. Seventy years ago, Naunyn was convinced that ascending infection in the biliary tract, when there was stasis, led to stone formation. Bacteria can be isolated from gallbladders containing stones removed at operation in over 50 per cent of the patients and from 20 per cent of stones. *Streptococci*, *Escherichia coli* and various members of the typhoid group are found most frequently, but a wide variety of organisms may be encountered, including *staphylococci*.

Stasis. The role of stasis of bile alone in calculi formation has not been determined. It has been observed that there is a tendency for stone formation among those in whom there is evidence of comparative stagnation

total number of female subjects, there will remain a number of women approximately equal to the number of male subjects. For example, of every five patients with gallbladder disease four will be women and one a man, three of the women will have been pregnant, one will not have been. These conclusions are derived from studies made over the past fifty years. It is probable that as the old-age group comes to constitute a greater proportion of the population, the ratio of gallstones in women who have not been pregnant and in men will increase.

Stones in the biliary tract seem to increase in size with the lapse of years. The presence of one or several stones seems to predispose to the formation of additional stones. Not only do the stones seem to increase in size and number, but also they appear in locations other than the gallbladder. Indeed, stones may form in the gallbladder or in any part of the ductal system. Most of the stones form in the gallbladder, but, as time passes, more subjects are found to have stones in the ductal system. The size of the stones in the common duct of a person eighty to ninety years of age is unquestionably greater than that of the stone obtained from a younger patient.

Stones may be found in the biliary tract from birth to death. They are rare in infants, infrequent in children and adolescents, occasionally found in young adult males and in females who have not been pregnant, very common in all women recently pregnant, and they occur with gradual and increasing frequency in each decade of life of older individuals.

Relationship of Gallstones and Biliary Tract Disease. Gallstones are associated with the majority of disorders of the biliary tract encountered among the people of America. Thus in the consideration of biliary tract disorders, one may more concisely present a comprehensive picture of the subject by first following the natural course of gallstones and noting specifically the instances in which calculi are not involved or are relatively unimportant. Briefly stated, we may begin with stone formation in the gallbladder—the usual site of origin of most gallstones. It is true that cholecystitis, either acute or chronic, may occur without calculi formation, but such instances are relatively few. In the usual patient, stones in the ductal system are observed to appear and produce symptoms at varying periods after cholelithiasis has occurred. There is much evidence to indicate that the incidence of choled-

cholithiasis increases appreciably each decade after stones have appeared in the gallbladder.

To find stones in the common duct and none in the gallbladder is relatively rare. More frequently, some time following cholecystectomy, stones are found in the ductal system that were either overlooked at operation or formed subsequently. Common duct obstruction, the result of benign stenosing fibrosis of unknown cause but frequently associated with a history of cholelithiasis, is an extremely rare entity. In the majority of subjects, postoperative stenosis of the common duct is the result of injury to that structure when cholecystectomy was performed.

Another important relationship between gallstones and biliary tract disease is that existing between gallstones and liver damage, generally labeled cirrhosis. Probably no single mechanism accounts for the numerous variations of impaired liver function that result from cirrhosis. The variations appear to range from minimal derangements which are difficult to recognize clinically to complete liver failure. Liver damage is of great concern because much of the risk in undertaking surgical operations for biliary tract disease arises from impaired liver function. Almost 50 per cent of carefully prepared patients who die following operations on the biliary tract exhibit advanced liver damage.

When there has been long-standing disease of the gallbladder, there are changes in the ductal system and the liver. It is believed that calculi, obstruction and infection in the gallbladder produce an inflammatory process which extends throughout the ductal system to involve the liver cells, probably by way of the lymphatics. This has been labeled "cholangitis" and may vary in degree from minimal involvement evidenced only by edema microscopically to gross suppuration. Some scarring results from each episode of inflammation and therefore, over the years, there is an accumulative injury to the liver that may eventually result in full-blown biliary cirrhosis. The exact role and significance of the presence of calculi, infection and stasis or obstruction are difficult to establish because cholangitis may be the result of blood-borne infection from the portal or systemic circulation. An early example of this is to be observed in the young woman recently pregnant who has an attack of acute cholecystitis with a mild degree of jaundice. This attack is due to cholangitis which in-

that colic may occur when there are stones in the gallbladder or biliary tract or when the gallbladder is inflamed, with or without stones; (3) that the afferent nerve supply from the gallbladder and extrahepatic bile ducts is through the right and left splanchnic nerves to the posterior roots of T7 through T10; (4) that the more severe the pain, the greater is the area referred to by the patient. For example, the pain may begin in the epigastrium and as it increases in severity may be felt by the patient to be extending along the costal margin into the back and up beneath the right scapula and shoulder and then to the substernal area and sometimes to the left precordial region, left costal margin and left shoulder.

Attacks of biliary colic, acute cholecystitis, and cholangitis may justify a diagnosis of gallstones. The demonstration of cholesterol and calcium bilirubinate crystals on microscopic examination of bile obtained from the duodenum by intubation is further evidence in establishing their presence. However, cholecystography according to the method devised by Graham and Cole in 1924 is by far the most widely used and the most satisfactory means of demonstrating directly or indirectly the presence of calculi in the gallbladder. The patient is given a dye (tetraiodophenolphthalein) that is excreted by the bile. The normal gallbladder concentrates the dye and may be visualized on the x-ray film. A diseased gallbladder does not concentrate the dye and, if the cystic duct is blocked, the dye will not enter. If there are stones in a gallbladder that has good function, they will be readily visualized. If the gallbladder is not visualized because of a lack of function or because the cystic duct is blocked, it may be assumed that the organ is diseased and contains stones. Cholecystography properly done will enable one to confirm the absence or presence of gallbladder disease in 90 to 95 per cent of the subjects (Fig. 3).

Recent developments in the technique of cholecystography, including intravenous administration of dye substances containing a higher iodine content, have made it possible to visualize the intact biliary ductal system and demonstrate stones and other abnormalities.

CHRONIC CHOLECYSTITIS

Chronic cholecystitis is a term designating disease of the gallbladder characterized by evidence of a chronic inflammatory process on gross or microscopic examination. Gall-

bladder function, as demonstrated by cholecystography, is usually impaired, but this is not always the case. Stones are present in a high percentage of the patients (Fig. 4). The term is a wide and comprehensive one and ranges from the process in which chronic inflammation is attended with minimal changes and vague symptoms of dyspepsia to that in which the gallbladder wall has been reduced to dense scar tissue contracted over calculi, the gallbladder is without function and frequently choledocholithiasis and liver damage are associated. Between these two extremes there are inexhaustible varieties and combinations of pathologic changes. The gallbladder with minimal microscopic involvement usually produces few symptoms, but this is not invariable, and occasionally such a gallbladder gives rise to severe symptoms. The most frequently encountered example of chronic cholecystitis is that of the patient who has had for months or years indigestion manifest by discomfort after eating. If a larger amount of food than is usual is ingested or if food high in fat content is included, there is, in addition, belching and regurgitation for several hours. These symptoms may increase to be followed by pain and colic with nausea and vomiting. The duration of such episodes may be short or prolonged over hours or days. Many of these patients have had repeated episodes of acute cholecystitis. Some, however, may never have had an acute inflammatory process involving the entire organ. Rather, the condition is believed to have been a slowly extending low-grade infection.

Symptoms. In early adult life, the symptoms may be of little concern to a patient when they first appear. Over a few years they may increase so insidiously that the exact time when they began to cause actual disability is difficult to determine. Under such circumstances, patients tend to accept their symptoms as something they must tolerate. They learn to keep them to a minimum by avoiding overeating and by abstinence from an ever-increasing number of foods that they correctly or incorrectly believe cause their complaints. Many patients are little disturbed by these symptoms throughout their more robust years of life. During this period, the changes of biliary tract disease, namely, increase in number and size of calculi, scarring of the gallbladder wall and reduction in functional efficiency of the gallbladder, progress and, what is probably of greater significance, there is injury to the liver which may range from

Figure 3. Cholecystograms made following the oral administration of the dye. A, Normally functioning gallbladder B, Gallbladder with numerous nonopaque calculi and fair function

of bile, as in pregnant women, obese individuals and those with organic obstruction to bile flow. As Naunyn pointed out, stasis and infection are frequently associated and this combination may provide the nucleus for stone formation.

Diagnosis. Gallstones usually give rise to a group of symptoms which render their presence evident. The sudden onset of pain in the epigastrium or near the right costal margin which radiates through to the back and sometimes to the right shoulder is typical of "gallstone colic." The pain is usually severe and may be agonizing. Its duration varies from minutes to hours and sometimes days. It may subside as quickly as it appeared, but there commonly exists a residual soreness in the area. The majority of attacks come on several hours after eating and at night. Large meals, and those containing considerable fat such as the typical American Sunday dinner consisting of meat,

potatoes, fatty gravy and ice cream, are believed to play an important role in precipitating an attack. If the pain persists, nausea and vomiting often accompany it. The severity of the pain is characteristic and enables one to distinguish it from that due to other conditions encountered in this region. The patient is reluctant to move or take a full breath. If the pain persists, he or she may become despondent as did Sir Walter Scott, who after an attack of many hours, "called his family and bidding them farewell turned his face to the wall to await death." Sir Walter Scott's attack, however, subsided and the poet went to sleep to awake the next morning in fair spirits.

The mechanism whereby the pain of gallbladder colic is produced is not completely understood. Certain facts are known: (1) that, in the conscious patient, distention of the gallbladder or any part of the ductal system by a rubber balloon causes pain, (2)

disturbance or chemical irritation. Of these, the most significant is infection.

Role of infection. There are several channels through which infection may involve the gallbladder; these are through the bile, the blood stream and the lymphatics and by direct extension from adjacent viscera. In addition, there may be an ascending infection via the ductal system from the duodenum. Once the gallbladder is infected by bacteria, it may become the focus for infection which may manifest itself in different ways in various parts of the body, giving rise to arthritis, neuritis or other disability. Sometimes the removal of a gallbladder which has been the site of long-standing infection is followed by a relief of symptoms due to affection in some other portion of the body. The role of infection in the pathogenesis of chronic cholecystitis has been subjected to numerous interpretations.

INFECTION FROM BACTERIA IN THE BILE. Many different bacteria are known to pass through the liver and into the bile. Many of these are destroyed or rendered inactive in the bile, while others seem to live, grow and seemingly are uninhibited. These bacteria may be grown from bile obtained at operation and include *Escherichia coli*, staphylococci, streptococci and typhoid groups. In acute cholecystitis without stones, the incidence with which positive cultures are made from material such as the wall of the gallbladder, the bile or the sentinel glands is rather high. And although the incidence is far less in the gallbladder of chronic cholecystitis, the same general bacterial groups are to be found. It is likely that if we had adequate means of taking material for culture from the ductal system, the gallbladder or the bile when there was no gross evidence of disease, the same organisms would be demonstrated. One may properly question whether the presence of such bacteria is pathologic or of clinical significance. Rolleston points out that in typhoid fever the bacilli are always present in the gallbladder but that cholecystitis is comparatively infrequent. I have removed the gallbladders from patients who were known typhoid carriers and whose bile prior to operation contained *Salmonella typhosa*, at operation the gallbladders were found to be normal both on gross and microscopic examination, but they did contain *S. typhosa*. Postoperatively these patients were free of this microorganism.

One may reason that as bile is concentrated in the gallbladder the number of organisms may be increased and that where

stasis is present for any reason optimum conditions would exist for the active invasion of the tissues by what may be considered passive organisms under other circumstances. There are many factors which may play a role in this process. There are the nature and virulence of the organisms as well as their actual number or concentration. One would need also to consider the over-all condition of the individual as to general resistance and susceptibility. Injury to the wall of the ductal system varying from that produced by simple distention to that sustained from a direct blow or piercing wound may provide the minimum needs for the invasion by these organisms to produce a clinical infection. The placing of large numbers of what have been considered as virulent organisms into the lumen of a gallbladder in animals has only infrequently produced cholecystitis.

One may conclude that many different bacteria are normally found in the biliary tract. In various types of cholecystitis—acute, chronic, calcareous and noncalcareous—there is ample evidence that these organisms may be playing an important role in the process. Certainly they are to be found in the bile, the wall of the gallbladder, the wall of the bile duct, in the smaller radicles of the liver causing cholangitis, and in the lymph glands such as the one that drains the gallbladder, the sentinel gland adjacent to the cystic duct and cystic artery.

HEMATOGENOUS INFECTION OF THE BILIARY TRACT. The arterial blood is supplied to the liver by the hepatic artery. The cystic artery, a branch of the hepatic, supplies the gallbladder and some individuals have small vessels passing directly to the gallbladder from the hepatic artery. In severe bacteremia, organisms may be found in both the liver and gallbladder as well as in other locations throughout the body. Under such circumstances, there may be multiple metastatic infections evidenced by true abscess formation. These may involve any system, organ or tissue throughout the body. The mechanisms which determine whether staphylococci that gained their primary focus in the throat may cause osteomyelitis or acute fulminating cholecystitis are not understood. There are plausible theories advanced Wilkie observed the appearance of gallstones and acute cholecystitis in rabbits that were given intravenously large numbers of bacteria grown from the biliary tract of patients with biliary tract disease. Such observations do not establish a relationship

Figure 4. Chronic cholecystitis with cholelithiasis A, Diseased gallbladder containing stones B, Line drawing to emphasize anatomic relationships

negligible damage to frank cirrhosis. Undoubtedly there are instances in which the process seems to subside and the patient appears to have been symptom free for years. If stones are present, the patients are candidates for an obstructive type of acute cholecystitis which is one of the most frequent conditions leading to abdominal operation in persons over sixty-five years of age. Although these individuals may not have been aware of symptoms, they have had progressive injury to their liver and, if this has been considerable, they may be poor operative risks when they present themselves for surgery. Such situations are frequent because many patients with chronic cholecystitis are able to tolerate their symptoms for years and only when the degree of

disability becomes marked do they seek relief.

Diagnosis. The diagnosis of chronic cholecystitis associated with cholelithiasis is established by a history of the symptoms as listed above and the demonstration of cholelithiasis and/or the impairment or absence of function. Cholecystography is one of the most accurate aids in diagnosis. With careful and proper evaluation, chronic cholecystitis and cholelithiasis may be accurately diagnosed in over 95 per cent of the patients.

Chronic cholecystitis without stone may be difficult to diagnose. Its pathogenesis is important.

Pathogenesis. It is believed that most cases of chronic cholecystitis with or without stones are the result of infection...metabolic

On microscopic examination the cholesterol is to be seen within the epithelial cells of the mucosa and beneath them in large macrophages. It is very easy for one to reason that this condition portrays a phase in the development of cholecystitis.

Role of chemical irritation. Derangement of the normal chemical reactions in the gallbladder may lead to irritative substances that play a role in the development of chronic cholecystitis. Ordinarily, acidification of the bile occurs in the gallbladder; if it does not, calcium carbonate is precipitated. The presence of calcium carbonate is indicative of irritative chemical activity and this compound may constitute a nidus for the precipitation of other constituents of the bile.

MILK OF CALCIUM GALLBLADDER. Calcium carbonate in almost pure form may be found in the gallbladder as a milk-white paste. It may or may not be accompanied by stones but is almost invariably associated with microscopic changes in the gallbladder wall that justify a diagnosis of acute or chronic cholecystitis. On x-ray films the calcium material may be seen outlining the entire gallbladder or concentrated in the fundus. In cholecystography there is poor concentration of the dye. If calculi are present they may be laminated because of deposition of calcium over a previously formed cholesterol stone. These produce a spectacular picture on the x-ray film with the laminated calculi displacing the more dense milk of calcium or calcium carbonate.

CALCIFICATION OF THE GALLBLADDER. In the aged with long-standing biliary tract disease, the gallbladder may appear to be calcified on x-ray examination. Such a gallbladder usually contains stones with laminations of calcium and there are varying degrees of calcium deposition in the wall. The origin of the calcium is believed to be from the bile and gallbladder mucosa. At operation the gallbladder is almost stonelike. It may be enlarged with a thickened wall and contain many stones or it may be small and contracted over one or a few small stones. In either event the likelihood of associated malignant disease is great and should be looked for both on gross and microscopic examination. The calcified gallbladder containing calculi cemented together with calcium carbonate is an impressive lesion at operation. It may be considered as due in part at least to derangement of the normal chemical change that goes on within it.

HYDROPS OF THE GALLBLADDER. It is probable that hydrodrops of the gallbladder is an

other example of cholecystitis due to chemical derangement secondary to obstruction of the cystic duct. This may be due to stones in the valvular portion that had their origin in the gallbladder. Hydrops may occur. It may occur in the absence of infection or stones and without evidence of changes in the cholesterol metabolism. The cystic duct is obliterated by scar tissue and is likely the basis of this condition. The bile can no longer enter the gallbladder, but the mucous cells continue to secrete. The gallbladder becomes enlarged and distended with a viscid-like mucus. The wall is thin but edematous grossly, and on microscopic examination a single layer of epithelium is seen lining it.

Differential Diagnosis. The differential diagnosis of chronic gallbladder disease requires careful evaluation of the patient's history and correlation with the findings on physical examination and the laboratory data, including x-ray examinations such as gastrointestinal series and intravenous pyelograms. The demonstration of gallbladder disease by cholecystography does not exclude the possibility of other conditions as the cause of symptoms referred to the epigastrium. The more common of these are peptic ulcer, renal disease, lesions of the large bowel including diverticulitis and neoplasm, pancreatitis and diaphragmatic hernia. The association of gallstones and heart disease has long been recognized. Stewart and Patterson have recently re-emphasized that the differential diagnosis between the two may be difficult, that the two may co-exist, and that when they do cholecystectomy often reduces the symptoms due to coronary disease.

Treatment. The treatment of chronic cholecystitis with cholelithiasis is surgical. Long experience has demonstrated that if stones are removed from a gallbladder and the organ remains, stones are likely to form within a period of months. Cholecystostomy for the removal of stones had been a common practice prior to Langenbach's report of cholecystectomy for chronic cholecystitis and cholelithiasis in 1884. Not long thereafter, Kummell (1890) reported an exploration of the common duct with removal of stones. Over the past seventy-five years an increasing experience coupled with improved facilities has made surgical treatment of biliary tract disease less difficult. Operative procedures are now well standardized and when carried out in carefully selected and well-prepared patients are associated with minimal risk.

Indeed, the over-all mortality for chole-

between the biliary tract disease in the human being and that found in the rabbit. Nevertheless, one is not justified in saying that there is no relationship or that bacteria isolated from the gallbladder of a human being may not be grown in the blood stream of the experimental animal and be found in considerable concentration in its biliary tract.

SPREAD OF INFECTION THROUGH ADJACENT LYMPHATIC SYSTEMS WHICH INTIMATELY ANASTOMOSE WITH THOSE OF THE BILIARY TRACT The lymphatics of the liver and of the biliary ductal system, including the gallbladder, are connected by a luxuriant network of anastomosing channels with those of the duodenum, right colon and appendix, pancreas and lower stomach. Although there have been many investigations of these lymphatics, their true importance has been neglected. The commonly known facts are that the lymphatics here as elsewhere are concomitantly associated with the blood vessels both arterial and venous. In the lower stomach, duodenum and large bowel, they conform to those elsewhere in the gastrointestinal tract. The structure is much the same in the extrahepatic biliary ductal system and gallbladder. The intrahepatic lymphatics, however, are a part of the complexity of the liver. These delicate tubules it is believed, provide the channels for the transportation of protein from the interstitial spaces of the liver to the blood vessels. When functioning to capacity and filled, they are evident structures, but in the experimental animal and after death they are difficult to visualize. In their fine ramifications these lymphatics surround the functioning liver cells. If this concept is kept in mind one can readily imagine how simply infection due to organisms that may have their primary focus at some distance, as for example in the appendix, may spread in the liver and biliary tract. There are, it is believed, many protective mechanisms with which we are not familiar that tend to prevent the extension of these infections.

The mechanism that is evident in an attack of acute cholecystitis is of importance in considering the relation of gallstones and liver damage. Disregarding for the moment the origin of gallstones and recalling that bacteria may be obtained from the gallbladder wall, the bile, the stone and the lymphatic glands in chronic biliary tract disease, then it is easy to understand how the stone, providing trauma and irritation, may play a role in repeated episodes of inflammation

within the gallbladder in which infection extends via the lymphatics to the liver and in turn leads to liver cell injury and scarring. The liver with its ability to recover from such insults and even to "regenerate by hypertrophy" may for a long time tolerate these episodes without clinical manifestations. On the other hand, the degree of liver involvement may at times be sufficient to cause jaundice. This is seen in young women with acute cholecystitis who have recently been pregnant. These patients may be so jaundiced that the bilirubin rises to 3 mg per 100 cc. of blood serum. This possibility should be kept in mind and the jaundice should not be considered as evidence of a common duct stone. Over the years a patient with gallstones may never be free from low-grade cholangitis and hepatitis resulting from an infection in a gallbladder containing stones. Eventually, the amount of liver injury may become clinically evident as cirrhosis. When reduction of the functional capacity of the liver has not been recognized and the patient is subjected to an operative procedure, hepatic failure may occur.

Liver damage associated with biliary tract infection and calculi is believed to be best explained by extension and reinfection through the lymphatics. A fair proportion of the deaths which follow surgery on the biliary tract are due to the liver damage that is the result of long-standing gallstones.

Role of metabolic disturbances. Metabolic disturbances may be the basis for chronic cholecystitis as well as for the production of stones in the gallbladder. It is possible that these disturbances may occur and be the cause of chronic cholecystitis without stone formation. There is considerable evidence that disturbance in the metabolism of cholesterol is one of the most important of the metabolic anomalies.

CHOLESTEROSIS. The deposition of plaque-like accumulation of cholesterol on the mucosal surface of the gallbladder is known as cholesterosis of the gallbladder. It is believed that while this is seen in a normal and well-functioning gallbladder it may be seen also in association with chronic cholecystitis. Because the cholesterol plaques are opaque yellow-white and are attached to the deep red mucosa, the term "strawberry gallbladder" has become synonymous with cholesterosis. Although these cholesterol deposits may be related to calculi formation, the relationship has not been clearly established. It is doubtful if symptoms or clinical signs are produced by this condition.

examination, the entire organ is seen to be involved by the acute inflammatory process; scattered areas of ischemia and necrosis are noted.

Acute cholecystitis may occur in the absence of calculi and accounts for 5 to 10 per cent of reported cases. There are several etiologic factors that contribute to this condition. They include bacterial infection that is derived from the liver, the blood stream and the lymphatic channels. Regurgitation of pancreatic juice is held by some to be of importance, as is also the reaction produced by bile-salt concentration within the gallbladder. Then there are circulatory disturbances such as arteritis and arteriolitis seen in association with terminal hypertensive cardiovascular disease and severe bacteremia.

There is frequently a history of a systemic infection due to one of many organisms such as *Escherichia coli*, staphylococci and hemolytic streptococci. An upper respiratory infection with superimposed secondary invaders is, for example, more frequently a precursor than is a localized infection such as osteomyelitis. An infection caused by a virulent organism which overwhelms the body resistance no matter where it gained its foothold may be accompanied by acute cholecystitis. In years past, typhoid fever was a classical example of this.

An attack of acute cholecystitis in a gallbladder without stones is less sudden in onset. There is discomfort and then pain in the hepatic region with anorexia in the beginning. As the pain increases the area becomes

Figure 5. Acute cholecystitis with stone impacted in the ampulla of the gallbladder. A, Photograph of specimen with stone in the ampulla and marked degenerative change. B, Photomicrograph ($\times 20$). Acute inflammation of the gallbladder wall with necrosis.

cystectomy for chronic cholecystitis with cholelithiasis is less than 1 per cent. If operation were to be done in these same patients when the diagnosis was first established, it might be reasonable to expect the present operative mortality rate to be reduced by 50 per cent. The basis for this statement is that in a study of deaths (sixty-six) following 3439 operations for nonmalignant disease of the biliary tract, the largest single cause of death was hepatic insufficiency resulting either from acute or chronic infection, necrosis or combinations of these factors. There were nineteen deaths, or 30 per cent of the total, due to hepatic insufficiency. Hepatic insufficiency is but one of the results of long-standing disease.

The problem of chronic cholecystitis without stones is sometimes a difficult one. If there are gross changes, such as thickening of the gallbladder wall, scarring and distortion, even though there are no stones encountered at operation in a patient in whom a diagnosis of chronic cholecystic disease has been established, cholecystectomy should be done. However, the removal of a gallbladder without stone is so frequently followed by persistence of the presenting symptoms that we are reluctant to do a cholecystectomy unless we are convinced that the changes are definite. Actually, few gallbladders are removed for chronic cholecystitis without stones.

Another problem that is encountered with increasing frequency, because a greater proportion of our population is being subjected to periodic complete clinical evaluation including cholecystography, is the demonstration of unsuspected cholelithiasis. Because one cannot predict the future course of the "silent stones," which may cause obstructive acute cholecystitis of a rapidly fulminating type in the older age group, and because of the low mortality rate associated with cholecystectomy in such patients, operation is indicated.

ACUTE CHOLECYSTITIS

Acute cholecystitis is often superimposed upon chronic cholecystitis that is associated with cholelithiasis. However, the acute phase of the disease may also appear as the primary involvement of the biliary tract and it may develop in the absence of stones. In contrast to chronic cholecystitis, the acute type presents the clinical manifestations of an acute inflammatory or obstructive process. Though the acute attack usually subsides, it can progress and, if it does, may result in

perforation, abscess formation or local or generalized peritonitis. In addition to involvement of the gallbladder, there is almost always extension of the infection to the biliary ductal system, namely, cholangitis of varying degree. Each episode of acute cholecystitis results in some injury to the liver.

The clinical diagnosis is established by careful evaluation of the patient's history, of his symptoms and of the signs elicited on examination. In the typical case, a fairly long history of recurring episodes of biliary colic frequently precedes the onset of the acute attack, in some subjects, however, there is no record of previous symptoms referable to the gallbladder. The pain is severe, is located in the midepigastrium and the right upper quadrant and may radiate to the shoulder or back. Nausea and vomiting frequently accompany the onset of pain in these patients.

The physical examination reveals marked tenderness and sometimes muscle rigidity in the right upper quadrant. The gallbladder may be palpable as a distended tender mass. The patient looks ill and has a rapid pulse, some fever and an elevated leukocyte count. Some patients whose attacks have lasted more than twenty-four hours have a mild degree of jaundice. There is considerable variation as to clinical findings among patients with acute cholecystitis, particularly in those of the older age group. Some have no fever, others no leukocytosis and in still others there may be little tenderness over the enlarged and palpable gallbladder.

At operation the gallbladder is found to be reddened and distended, its wall is thick and edematous. Besides one or more stones the organ usually contains bile mixed with blood, colorless bile or pus under pressure. Usually there is a stone lodged in the ampulla of the gallbladder (Fig. 5) or the entrance of the cystic duct, blocking the outflow. On close inspection, areas of necrosis and gangrene may be noted and in some a frank perforation will be found with inflammatory reaction about the entire gallbladder and adhesions to neighboring structures. Free perforation with general peritonitis also may occur. The favorite location for such a perforation is in the fundus. This avascular area in the presence of inflammation of the gallbladder and compression of its blood vessels is most likely to become gangrenous first. Necrosis of this portion of the gallbladder in the presence of increased intracystic pressure may early result in perforation and escape of the contents into the abdominal cavity. On gross

tis is surgical. There has been considerable controversy during the past twenty years as to when surgery should be embarked upon; however, the trend has been toward early operation. Some prefer to encourage the subsidence of the attack by keeping the patient quiet, allowing nothing by mouth and keeping the stomach decompressed with an indwelling tube, and then at some later time removing the gallbladder. We prefer early surgical treatment of acute cholecystitis rather than the delayed.

The early surgical treatment consists of cholecystectomy or cholecystostomy as soon as the patient has been so prepared as to be considered in optimum condition for operation, unless there is some condition present which is not immediately reparable and which contraindicates operation.

Although cholecystostomy is the procedure of choice in acute cholecystitis, the surgeon should keep an open mind as to just what is to be done until he has evaluated the findings. Cholecystostomy, a lesser procedure, may be indicated in the presence of peritonitis following a perforation of the gallbladder, when the inflammatory process obscures the anatomic relationship of vital structures in the biliary fossa, in the presence of severe jaundice due to common duct obstruction and when the general condition of the patient is so grave that a general anesthetic and a prolonged operative procedure are contraindicated. Cholecystostomy under such circumstances is a compromise procedure but may be lifesaving, tiding the patient over a critical period. Definitive surgery, that is, cholecystectomy, should be done a few months later. Choledochotomy may sometimes be indicated in the presence of acute cholecystitis, particularly in patients of the older age group, in addition to cholecystectomy or cholecystostomy. The usual indications for choledochotomy are both less easily recognized and not as reliable in the presence of acute cholecystitis. Jaundice is frequently unassociated with choledocholithiasis, dilatation and induration of the common duct are difficult to evaluate because of inflammatory reaction, and stones are not as readily palpable for the same reason.

Acute cholecystitis constitutes a problem of varying importance and urgency, depending on whether it occurs as an early phase of biliary tract disease, in a young woman recently pregnant, for example, or as an episode in the later stages of chronic biliary tract disease, as with men and women in the older age group, or as a complication of a

terminal systemic disease or following some operative procedure unrelated to the biliary tract. For acute cholecystitis in the young, recently pregnant woman, since the post-operative morbidity of complications and the mortality rate are minimal and the complications of perforation and peritonitis are infrequent, we believe that operation is the best method for interrupting biliary tract disease and that early surgical treatment should be employed. In both women who have not been pregnant and men in a slightly older age group but still under the age of fifty years, acute cholecystitis appears to be a somewhat more severe process. Complications under nonsurgical treatment are more likely to occur, but this group will tolerate operation almost as well as the first unless they are suffering from some systemic involvement such as cardiovascular disease, diabetes or renal impairment. A third group consists of those over fifty years of age, the majority of whom have a long history of biliary tract disease. The older the patient and the longer the duration of biliary tract disease, the more common are the complications of acute cholecystitis if not treated by surgery. By and large, the older the patient the more difficult it is to estimate the exact nature of the process by physical examination, temperature elevation or white blood cell count and thereby determine whether the wall of the gallbladder is gangrenous, or whether perforation is impending. Furthermore, the incidence of common duct stone is greater in the older group. These patients are also more prone to develop postoperative complications which contribute to a higher mortality rate. Here again, however, early surgical treatment is the best protection for the patient.

In a final group are those patients who develop acute cholecystitis as a complication of the terminal phase of a systemic disease, such as cardiovascular disease with marked arteritis and arteriolitis. Whether or not operation is justified for such patients depends chiefly on the probable expectancy of life at the time. Since this is extremely difficult to estimate, and since catastrophic perforation of the gallbladder with resulting bile peritonitis can be averted by cholecystostomy performed with the patient under local anesthesia, surgery to us seems indicated. When acute cholecystitis develops as a complication following operation for conditions unrelated to the biliary tract, the problem is primarily one of diagnosis and the type of surgical treatment is dependent upon the

tender and the gallbladder enlarges. Although there may be waves of increased pain similar to that due to biliary colic, such is not the common course of events. Systemic manifestations such as temperature elevation and leukocytosis are present. As the gallbladder enlarges, the peritoneal reaction increases and the local signs become marked. In many instances the peritoneal reaction is indistinguishable from the reaction produced by a perforation. Sometimes, patients operated upon for presumed perforation have been found to have noncalculous acute cholecystitis with a very flagrant and intense inflammatory process which extends to and involves the adjacent viscera and omentum.

The gallbladder in the early hours of an attack is edematous, there is a rapid increase in thickness of the wall of the gallbladder and obliteration of the cystic duct. The cystic duct may be occluded so that no bile enters it and none is emptied through it into the common duct. On microscopic examination, edema is noted as well as polymorphonuclear infiltration about the vessels. Bacteria may be demonstrated in these tissues. As the process progresses the organ becomes injected, distended and tense and the wall phlegmonous. Ischemic areas become apparent and necrosis with perforation may take place. In the beginning the bile in the gallbladder is normal in appearance and consistency. It may become diluted with thin mucoid material and then there may be hemorrhage. Usually the same organisms are to be obtained from the bile as are found in the wall or sentinel gland. At any point in this inflammatory reaction the process may subside either because of the natural resistant mechanisms of the body, a decrease in the virulence of the organism or specific chemotherapy.

Following the subsidence of an initial attack, there is healing of the ulcerations of the mucosal surface and scarring of the wall. Depending on the amount of tissue destroyed by the infection, the function of the gallbladder may be impaired. This may be so slight that it is of no particular importance or it may be so marked that the gallbladder is no longer capable of receiving or concentrating bile. In either event, this initial episode may be but the beginning of a long series of events in the advancement of biliary tract disease. It is likely that the organisms persist in the gallbladder and biliary passages and there will be recurrent attacks. The alterations in function and the residual

debris from the infection at its height may provide a nidus for gallstone formation.

Acute cholecystitis has been produced in animals by a variety of ways. A number of materials administered intravenously, such as Dakin's solution, have produced it. Bacterial toxins of pathogenic organisms have produced ulcerative lesions in the mucosa. Various substances have been introduced into the gallbladder directly in an attempt to duplicate the regurgitation of pancreatic juice or duodenal contents into the biliary ductal system and gallbladder. These substances have been introduced directly with a needle and have produced acute cholecystitis of varying degree followed by healing that completely obliterates any evidence of what took place. This may be of clinical significance in that it emphasizes the fact that the causative factors in biliary tract disease are likely to be long standing and persistent.

The reflux of pancreatic juice containing enzymes into the gallbladder is believed by some to be the cause of a fulminating type of acute cholecystitis. The mechanism for such a reflux requires that the pancreatic duct empty directly into the common duct and that there be some obstruction between this and the opening into the duodenum. Thus a stone in the ampulla of Vater or spasm of the sphincter of Oddi could provide the immediate cause for the reflux.

In descriptions of operative findings in patients with acute pancreatitis it is occasionally stressed that there was also acute cholecystitis. The degree of gallbladder involvement seems to vary greatly. Only minimal edema is described in some while in others the description of a well-advanced stage of acute cholecystitis has been reported. One could well consider that when the pancreatic duct joins the common duct proximal to the ampulla of Vater and there is an obstructive stone, bile might pass into the pancreatic ductal system and produce acute pancreatitis and at the same time a mixture of pancreatic juice and bile could be regurgitated into the gallbladder resulting in acute cholecystitis. This probably does occur and material removed from such gallbladders has been demonstrated to contain pancreatic enzymes. However, in a rather large series of patients I have treated surgically for acute cholecystitis it was by no means a clear-cut entity and is regarded as being very rare.

Treatment. Treatment of acute cholecysti-

Figure 7. Intravenous cholangiogram. A, Normal biliary tract. B, Stone in common duct and residual cystic duct remnant.

intensity of the jaundice vary greatly. We believe that a stone may be passed through the ampulla of Vater during an "attack of biliary colic." If the stone produces obstruction for a short time, and if there is little infection in the ductal system, there may be no elevation of temperature and no clinical jaundice. At the other extreme, if the stone is large, is not passed and causes complete obstruction, then there is prolongation of the pain with persistent tenderness in the right upper quadrant. If the stone remains engaged and obstruction is complete, the jaundice persists and becomes more intense. If it acts as a ball-valve mechanism, then there is a spontaneous subsidence of the symptoms, all of which tend to reappear within varying periods and whenever the stone blocks the flow of bile again, as described by Charcot.

The surgical removal of stones from the ductal system by incising the common duct just distal to where the cystic duct joins it

and exploring the intrahepatic tributaries provides our only satisfactory means of treatment. There have been numerous regimens elaborated in an attempt to increase the flow of bile and at the same time produce relaxation of the sphincter of Oddi and then flush the stones into the duodenum. These have been of little benefit. The surgical removal of stones is sometimes difficult because they are easily overlooked in the more inaccessible part of the ductal system. The greatest proportion of common duct stones is found in the distal portion of the choledochus near the ampulla of Vater. They may at the time of operation be located within the hepatic radicles and escape the most exhaustive search. Visualization of the ductal system by filling it with a radiopaque medium, such as Diodrast, and taking x-ray pictures (cholangiography) at the time of operation is a distinct aid in locating the elusive stone (Figs. 6 and 7). Recently the introduction of more concentrated contrast

local process and the patient's general condition. Probably surgical treatment during the early phase of cholecystitis, whether it be acute or chronic, is the best means of interrupting biliary tract disease.

CHOLEDOCHOLITHIASIS

If stones in the common duct are looked upon as a complication or sequela of gallstones, then it follows that the longer cholelithiasis has been present the greater is the likelihood of choledocholithiasis. The older the patient is and the longer the disease has existed, the greater may be the expected incidence of common duct stones. If all age groups are included and allowance is made for silent stones, not omitting the findings from autopsy studies, it is our opinion that the true incidence of retained common duct stones is about 10 per cent. In other words, of all patients with stones in the gallbladder, one in ten will also have stones in the common duct. Choledocholithiasis is seldom if ever demonstrated at operation in the presence of a normal appearing gallbladder without stones. The common sequence of events is that stones form in the gallbladder, then either pass into the common duct or form there. It is logical to assume that a stone which would pass through the cystic duct from the gallbladder would in turn travel through the common duct and ampulla of Vater. There are wide differences between what is possible and what actually takes place.

The incidence of common duct stone increases as the life span increases. Its occurrence is infrequent in patients with cholelithiasis under forty years of age (less than 6 per cent) and then gradually increases decade after decade so that in those over eighty years of age one-half of the patients with cholelithiasis may be expected to have choledocholithiasis. The number and size of the stones found in the older age group are likewise greater.

Because of the frequent coexistence of gallbladder disease and common duct stones, the presenting symptoms are often those of cholelithiasis. Unless the stones in the duct produce obstruction—complete, partial or intermittent—resulting in biliary colic and in jaundice, the symptoms are the same. Furthermore, a mild degree of jaundice (bilirubin of less than 3 mg. per 100 cc. of blood serum) is to be seen as the result of an exacerbation of cholangitis associated with an attack of acute cholecystitis without stones in the common duct. Stones in the common duct which do not cause obstruction and thereby do not result in jaundice may persist unsuspected for years.

The typical manifestations of choledocholithiasis are, in addition to those of cholelithiasis, episodes of jaundice following bouts of biliary colic. Following a period of pain and before jaundice is evident, there may be a chill and elevation of temperature. The duration of the pain, the severity of the chill, the elevation of the temperature and

Figure 8. Operative cholangiogram showing stones.

under these circumstances, however, does not necessarily indicate that common duct obstruction will result from them. It should also be mentioned that stones may exist in the common duct and yet not produce symptoms. However, the fact that a patient is without symptoms of common duct stones following cholecystectomy does not rule out their possible presence.

The patient who has cholelithiasis and choledocholithiasis following cholecystectomy and the removal of stones in the common duct may be completely well. After varying periods, some may develop signs and symptoms of common duct obstruction. At operation a stone or stones are again re-

moved. There then arises the question of whether these formed following the first operation or whether they escaped detection by the surgeon. There is ample evidence that either may occur. Stones may be overlooked and the patient have a typical attack of common duct obstruction within a few days. Re-exploration reveals a stone of good size. If the patient goes for months or years and then exhibits signs of obstruction, one may reason that small stones were overlooked at the first operation and that these gradually increased in size and eventually reproduced the original clinical picture. Then, of course, new stones may form and obstruction result. We have no means of

Figure 8 If common duct exploration is to be done at the time of a cholecystectomy, the gallbladder will serve a purpose if it is removed downward from the fundus. The cystic artery and the cystic duct are first identified and secured and the gallbladder then is dissected from its bed in the liver. The cystic duct is left intact with a ligature about it just distal to the ampulla of the gallbladder to prevent small stones from passing through the cystic duct into the common duct. After exploration of the common duct, if for any reason a free passage into the duodenum cannot be demonstrated, then transduodenal exposure of the ampulla through a longitudinal incision should follow.

materials, which may be given orally or intravenously, for visualization of the biliary tract before operation has been useful in identifying the number, size and location of calculi. Surgeons of experience in biliary tract disease are well aware of the probability of overlooking calculi and have developed various elaborate procedures in an effort to avoid this.

Exploration of the common bile duct and its tributaries for stones is a surgical procedure of sixty years' standing. One of the first to report its successful accomplishment

was Kummell in 1890. It is commonly employed today, but the frequency of its use varies greatly from one clinic to another. Some explore the common duct for stones only in the presence of certain indications, whereas others carry out choledochotomy almost routinely in conjunction with cholecystectomy for cholelithiasis (Fig. 8).

A review of the literature on this subject would lead one to assume that there is general agreement as to the indications for exploring the common duct. In fact, many authors list the same criteria. However, a wide difference is found in the frequency with which the duct is opened in quest of stones and in the incidence of calculi recovered. By and large, those who report the greatest proportion of explorations also report the highest incidence of stones recovered.

Table 2 tends to lend emphasis to this statement. McKittick and Wilson, for example, report 100 choledochotomies combined routinely with cholecystectomy for cholelithiasis and show recovery of stones in the common duct in 52 per cent of these subjects. The other extreme is the experience at The New York Hospital-Cornell Medical Center. Of the 4365 patients subjected to either cholecystectomy or cholecystostomy, choledochotomy in search of stones was done as well in only 522, or 11.9 per cent. Stones, however, were recovered in 61 per cent of those explored, or 7.3 per cent of the total series.

It is evident that there is considerable variation in the experience of surgeons who explore the common duct. Part of the difference may lie in the fact that when a gallbladder is manipulated at operation, small stones may pass through the cystic duct into the common duct and are then found when the duct is opened. Finding small stones

groups of patients. One is made up of patients usually in the older age group who have had no previous operation and who have rather uniform findings at operation as described above. Then there are those who have had, many years previously, a cholecystectomy and/or choledochotomy with relief from their symptoms for varying periods and then have developed jaundice in an interval varying from three months to seventeen years. Operation reveals diffuse or segmental fibrosing stenosis of the biliary ductal system.

The narrowing or obliteration of the ductal system to the extent that jaundice results constitutes a grave situation with poor prognosis. Although stricture may be produced by a primary neoplasm and diffuse inflammation, by far the most common cause

is operative injury. Almost invariably associated with stricture formation and its obstructive jaundice is infection. The two, once established, seem inseparable and together result in liver destruction which is incompatible with any degree of well-being.

The diagnosis of stricture due to operative injury is readily established. The original injury is usually either partial or complete interruption of the continuity of the common duct by actual division or ligation. The sequence of events following operation is therefore important. If the duct has been partially or completely divided and not ligated, profuse bile drainage becomes evident within a matter of hours and persists, if unmolested, for weeks or months. If the drainage ceases, jaundice appears. This is

STENOSIS OF COMMON DUCT INDICATING OPERATIVE REPAIR.

differentiating between the two. It is of importance, however, that they be removed whenever they occur regardless of previous operations because they can cause great disability and lead to rapid damage to the liver.

Obstructive Jaundice. Jaundice may be a difficult and perplexing problem to both internist and surgeon. Numerous laboratory tests have been developed in an effort to render diagnosis more accurate. There is a vast literature on the subject. Despite this we are frequently unable to arrive at a definite conclusion as to whether or not jaundice is due to common duct obstruction or some other cause.

Jaundice associated with a diminished amount or absence of bile in the intestinal tract may be caused by ductal obstruction or liver cell damage. If it is due to the former, then soon after it is established the increased intraductal pressure (to over 375 mm. of water) results in failure of the Kupffer cells to function. Thus there is only a short period when "pure" obstructive jaundice is to be found. In the latter, hepatitis, cirrhosis or toxic necrosis produces jaundice by eliminating the function of the Kupffer cells. Differentiation between these two is at times most difficult.

There is general agreement that each patient should be evaluated in a meticulous manner. Abnormalities should be sought for in the blood and corrected and the nutrition of the patient should receive immediate and continuous attention. Each step in the management of the patient with jaundice should be well planned and done with deliberation. For those patients who, after critical study, are felt to have obstructive jaundice, operation should be embarked upon when it is believed that all measures needed to bring his or her condition to the optimum for operation have been carried out. Delay based on the hopes that complete common duct obstruction will subside too often results in further liver damage. One of the most important contributions to the management of the jaundiced patient with an increased hemorrhagic tendency has been the introduction of vitamin K. Measured in terms of prothrombin time, the bleeding tendency is recognized in degree. When the liver parenchyma has not been destroyed, the administration of vitamin K corrects the bleeding tendency. The mortality following surgical operations upon jaundiced patients was formerly very high. Since the introduction of vitamin K by Dam and others in 1937, this hazard has been greatly reduced.

An increasing number of patients over sixty years of age are being seen with common duct obstruction due to large gallstones (Fig. 9). Because of long-standing biliary tract disease they also have liver damage. Delay in the relief of obstruction of the common duct is not well tolerated and should be kept at a minimum.

There is a group of patients who defy our diagnostic armamentarium and we are confronted with the question of operating to establish a diagnosis. This may be hazardous because death may follow in the patient who is suffering from severe hepatitis. On the other hand, improvement follows the removal of an unsuspected stone producing complete common duct obstruction. No rule of thumb seems practical; rather one must consider each such case individually with care and thoroughness and then do what he believes best.

STRICTURES DUE TO DIFFUSE INFLAMMATION AND INJURY OF THE BILIARY TRACT

Benign, diffuse, stenosing fibrosis of the ductal system is not frequent. However, from time to time the condition is encountered at operation and at post-mortem examination. The etiologic basis is not known. The onset is insidious and the development slow until jaundice has become definite and marked. Patients give a history of digestive disturbances similar to and undistinguishable from those due to gallbladder disease. Pain in the early course of the condition may be absent or insignificant. With the onset of jaundice, there is usually discomfort in the right upper quadrant and sometimes attacks of mild colic. The gallbladder is not visualized on cholecystography. At operation the wall of the gallbladder and the extrahepatic bile ducts are found to be thickened and appear edematous. The lumen of the common bile duct may be reduced to less than 1 mm. in diameter and will admit a small probe only with difficulty. The bile may vary from that of normal appearance to a colorless viscid mucoid material. On microscopic examination the liver reveals extensive biliary cirrhosis. Operation accomplishes diagnosis only and the progress of the disease continues until the patient dies because of impaired liver function. It should be emphasized that there is such great variation in the findings at autopsy and the clinical course in the reported cases that one is justified in wondering whether all the cases are due to the same process. There are two

widespread metastases. The next most common type, the papillary adenocarcinoma, is not as malignant. This tumor grows more slowly, is more bulky and metastasizes late. Its very nature, namely, that it grows slowly, often ulcerates and is associated with infection, occasionally results in its unexpected discovery at an operation for acute or sub-acute cholecystitis. Scirrhus adenocarcinoma of the gallbladder occurs slightly less frequently than does the papillary type. It possesses about the same degree of extension. Mucous adenocarcinoma and squamous cell carcinoma are also found in all reported series of carcinomas of the gallbladder and differ very little in their course.

Treatment. The surgical treatment in recent years provides for radical cholecystec-

tomy, including resection of the gallbladder bed. The surgical treatment of nondisseminated carcinoma of the gallbladder in recent years includes the resection of all the liver tissues which comprise the gallbladder bed en bloc with the gallbladder. The portal vein, hepatic artery and extrahepatic ductal system are identified and skeletonized with the resection of the peritoneum and retroperitoneal tissue near these structures and the gallbladder. Partial hepatectomy has been done in an attempt to completely extirpate the disease. The reported results are discouraging because at the time operation is undertaken about 60 per cent of the subjects will have spread of the disease beyond the local tumor. Less than half of those who have been considered suitable for surgical

CARCINOMA ARISING FROM EXTRA- HEPATIC BILIARY SYSTEM.

Figure 11

ary system. A, Photograph of advanced carcinoma of common bile duct invading the

associated with intermittent and colicky pain accompanied by chills and fever. If the obstruction is complete, the stools are acholic and the liver enlarges. There is anorexia and consequent loss of weight. If the injury at operation immediately resulted in obliteration of the lumen of the duct, as may occur by placing a ligature about the duct, then there follows increasing jaundice without bile drainage. Of course, there may be variations and combinations of these two types of injury. Sometimes a duct obstructed by a ligature may open and discharge bile and a fistula gradually contracts down to complete obstruction. Scar formation and adhesions near the site of injury increase as time goes on. Infection is commonly present and, together with the obstruction, is associated with cholangitis and subsequent liver damage.

Once the diagnosis has been established, operation should be undertaken when the patient has been adequately prepared. The operative correction may be difficult and is not a task for the novice or casual surgeon. If it is feasible, resection of the obliterated segment of the common duct and re-establishment of continuity by end-to-end anastomosis, thus preserving a functioning ampulla of Vater as advocated by Cattell, is the ideal procedure (Fig. 10). It is often difficult to locate the distal segment and duodenotomy with retrograde exploration of the duct through the papilla of Vater may be indicated. The duodenum must be mobilized in most instances to enable one to approximate the ends of the duct. Walters and his associates at the Mayo Clinic have reported considerable success with anastomosing the duodenum to the proximal segment of the common duct or even the hepatic ducts in the hilum of the liver. In an attempt to reduce the hazard of regurgitation of intestinal contents into the biliary tract, Cole has popularized the anastomosis of the proximal ductal fragment to the Roux en Y arm of jejunum. Hepaticojejunostomy has been described by Longmire for those patients in whom the proximal ductal system in the hilar area could not be identified. All these procedures leave much to be desired. Many surgeons, including Lahey, Walters, Cattell, and Cole, have made notable contributions to the surgical correction of stricture of the common bile duct due to operative injury. These are commendable. However, the best solution to the problems would seem to be their prevention. This is to be accomplished by careful surgery performed

by one who knows the variations of the anatomy of this area and the seriousness of common duct injury.

TUMORS OF THE BILIARY TRACT

The majority of tumors of the gallbladder and bile ducts are malignant. The few benign tumors which are encountered are sometimes difficult to distinguish from inflammatory responses such as hypertrophy of villi and reaction about calcareous material. Papillomas, adenomas and fatty tumors have been observed throughout the biliary system, they are rare, infrequently producing symptoms and occasionally diagnosed incidentally in the course of cholecystography.

The malignant tumors of the extrahepatic biliary tract include those which arise in the gallbladder, extrahepatic ducts and ampulla of Vater (Fig. 11). They are infrequently diagnosed before operation or autopsy. With the exception of those of the ampulla, they are extremely resistant to therapy and are associated with a short period of survival.

Carcinoma of the Gallbladder. Rolleston and McNee cite Maximilian de Stoll, Professor of Medicine in Vienna, as being the first to describe carcinoma of the gallbladder. He reported observations on three post-mortem subjects in 1771, but it was generally considered a rare condition until Graham stated, in 1931, that carcinoma of the gallbladder comprised 8 to 10 per cent of all malignant tumors found in women. Since that report, other studies have been published placing the incidence of this condition at about 4 per cent of all cancers. Carcinoma of the gallbladder accounts for 65 to 75 per cent of all malignant lesions of the extrahepatic biliary tract. The majority of patients with carcinoma of the gallbladder are over fifty-five years of age and more than 90 per cent have gallstones. The symptoms associated with this disease are indistinguishable from those of cholecystitis with cholelithiasis. Actually, since the incidence of stones is so high, it is suggested that the symptoms arise from the gallstones rather than from the malignant process. Although there are a few instances of survival of these patients beyond five years, the majority die within a year of the establishment of the diagnosis. Often the diagnosis of carcinoma of the gallbladder is made by the pathologist who examines the gallbladder removed because of stones. Most carcinomas of the gallbladder are of the infiltrating adenocarcinoma type, which rapidly invades all layers of the gallbladder and extends into the liver and produces

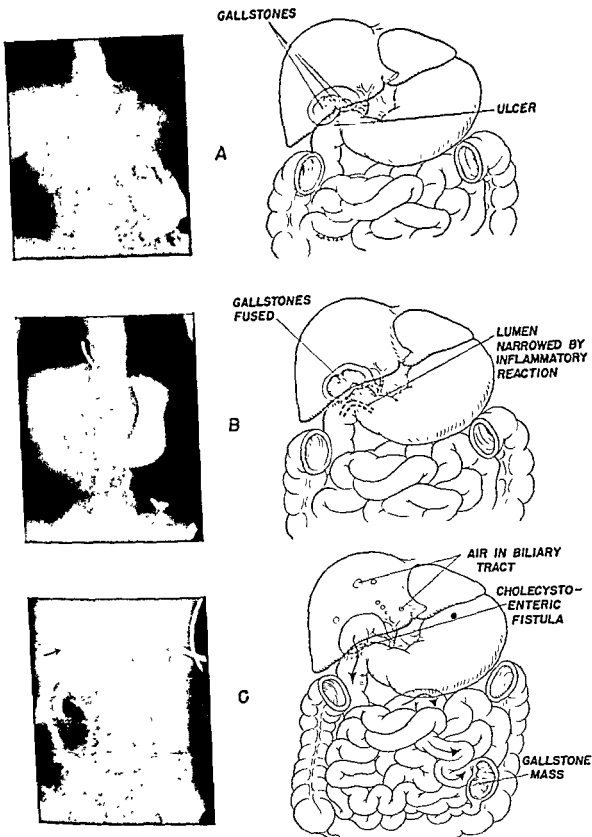

Figure 12. Ge
gallstones. B, Five
stones associated

reveals duodenal ulcer and incidental coalescence of previously noted gall-

ulting in almost complete obstruction

treatment have survived more than one year. There are a few reports of survival of five or more years.

Carcinoma of the Extrahepatic Bile Ducts. Carcinoma of the extrahepatic bile ducts includes tumors arising from the common bile duct, the cystic duct and the ampulla of Vater. Articles on these tumors and case records indicate that difficulty is often encountered in determining the exact site of the tumor's origin. Primary tumors of the pancreas or duodenum may also be confused with those arising from the ampulla of Vater. Renshaw credits Durand-Fardell with reporting the first case of cancer of the common duct in 1840.

Carcinoma of the common bile duct and cystic duct is much less common than that of the gallbladder, occurring about one-fifth as frequently. Half of these are associated with gallstones. Women and men are more equally affected than in carcinoma of the gallbladder, in which there is a ratio of 3:1 with predominance in the female. Resection of the tumor with restoration of ductal continuity is indicated. A few successful operations with several years' survival of the patient have been reported, but they too are rare.

Carcinoma of the ampulla of the choledochus has a far better prognosis than either that of the gallbladder or of the bile ducts. In our experience, and it parallels that of many other clinics, patients with carcinoma of the ampulla without spread treated by radical pancreatoduodenectomy have had a much longer survival period than do those with carcinoma of the gallbladder or bile ducts, many going over five years without evidence of recurrence.

Although stones are not found to be associated with carcinoma of the bile ducts as frequently as with carcinoma of the gallbladder, Marshall, Kirshbaum and Stewart have reported their presence in from 21 to 55 per cent of their subjects. This is a higher frequency than is found in nonmalignant disease. The role of stones and their association with carcinoma of the bile ducts is without adequate explanation thus far, but a derivative of cholic acid in the bile, methylcholanthrene, is known to be a carcinogen and may play a part.

Infiltrating and medullary adenocarcinomas compose the major type of tumors in this group. Leiter found the infiltrating type to be predominant in the common bile duct, with papillary adenocarcinoma most frequent in the region of the ampulla of Vater.

The recognition of these tumors at a resectable stage is difficult and depends largely upon a policy of early exploration in patients with mild or transient jaundice and upon a lively suspicion and acute observation of the operating surgeon. Cytologic examination of duodenal content has not been of much aid in preoperative diagnosis. Preoperative intravenous cholangiography may help to localize an incomplete obstruction of the common duct at the ampulla of Vater.

Except in rare instances, early diagnosis of these tumors is difficult and so is seldom made. Many tumors are discovered unexpectedly or in a late phase when they have extended and metastasized beyond any possible cure by surgical therapy. Untreated, the life expectancy of the patients after onset of the first symptoms, or from the time the tumor is discovered, is usually measured in months. But as interest in these tumors has widened, their recognition has increased and surgical therapy has been developed, first palliative and later curative.

Palliation has been directed toward relief of jaundice and its associated complications, and toward relief of pain. In carcinoma of the ampulla of Vater, pancreatoduodenectomy or similar more extensive radical resection is indicated in all individuals in whom excision of the gross tumor seems initially possible. Although the immediate postoperative mortality and complication rates are high, the palliation provided those patients who survive is long standing and effective. The absolute curability is probably not greatly affected. Resections known to be palliative seem justified in selected subjects.

The prognosis in patients with carcinoma of the gallbladder and extrahepatic biliary ducts is not greatly improved by the adoption of radical surgical procedures. Because of the high incidence of stones in these patients and because so many are over sixty years of age, prophylactic cholecystectomy for all patients with symptomatic biliary tract disease may be further justified on the basis of the dangers of malignant change.

GALLSTONE ILEUS

Intestinal obstruction due to gallstones and associated cholecystoduodenal fistulae have in recent years been reported with increasing frequency. McLaughlin collected reports of 366 cases from the literature in 1951. There have been several reports of small series stressing the higher incidence of this type of obstruction in the older age group. This is in keeping with the now rec-

Diseases of the Liver

By ARTHUR H. BLAKEMORE, M.D., and
ARTHUR B. VOORHEES, JR., M.D.

ARTHUR HENDLEY BLAKEMORE is a Virginian. Able men inherit additional distinction when born in certain states of the union. Virginians and Texans will dispute the inclusion of other states in that statement. The College of William and Mary and Johns Hopkins University were the sources of his education. He has led the revival of interest in operations for the relief of portal hypertension and the use of substitutes for resected, diseased blood vessels.

ARTHUR BOSTWICK VOORHEES, JR., was educated at the University of Virginia and trained to be a surgeon at Columbia University, College of Physicians and Surgeons, and Presbyterian Hospital, New York. He has been active in surgical research in problems of vascular surgery and portal hypertension.

PORTAL HYPERTENSION

The term portal hypertension can be applied to any state in which the blood pressure within the portal venous bed is above the normal range. There is no strict agreement as to the precise range of normal pressure or as to the best method of measuring the pressure. The clinician circumvents these uncertainties by basing his diagnosis on anatomic deformities known to be associated with portal hypertension. The surgeon is frequently in a position to validate the diagnosis by comparing direct portal pressure measurements obtained by a uniform technique performed before and after an

of water when the right atrium is the zero point

Etiology. Portal hypertension may be transient or constant, related to a definite pathologic state or part of a normal physiologic response. The major causes are:

- 1 Physiologic
 - a Hormonal (response to histamine, epinephrine)
 - b Increased intrathoracic pressure (response to Valsalva maneuver)
 - c Neurogenic (hepatic plexus stimulation)
- 2 Pathologic
 - a Reversible
 - Congestive heart failure
 - Bronchial asthma
 - Pericardial effusions

ognized higher incidence of acute cholecystitis in the aged and the tendency to develop complications without impressive clinical manifestations

In the majority of instances there is perforation of the gallbladder with the discharge of a stone or stones into the lumen of an adherent adjacent viscus, usually the intestine. If the stone is too large to pass through the intestinal tract it becomes lodged in the area where the lumen is smallest and produces a typical acute intestinal obstruction. Because the lumen of the ileum is the narrowest, it is a frequent site for obstruction. Stones perforating into the stomach may be vomited and those into the large bowel are passed in the feces

The common site for perforation is into the first or second part of the duodenum, leaving a residual fistula behind. If the stone obstructs the small bowel in its terminal portion a triad of findings is to be observed (Fig. 12) distended small bowel, a gallstone in the small intestine, usually in the terminal ileum, and air in the biliary tract.

Intestinal obstruction requires immediate surgical evaluation and, in most instances, operation. Intestinal obstruction due to a gallstone requires the same type of management. The commonly associated high mortality which has been reported should be reduced by proper supportive measures followed by operation. Because the diagnosis is incorrect in so many of these patients, the condition needs greater consideration in differential diagnosis of intestinal obstruction. If one keeps the triad, small bowel obstruction, gallstone within the small bowel and air in the biliary tract, in mind when seeing patients, particularly in the older age group, with intestinal obstruction the diagnosis may more frequently be made

Since it is rare for a stone which is large enough to produce intestinal obstruction to pass from the common duct through the ampulla of Vater, it should be assumed that a cholecystojejunal fistula exists. At a later operation cholecystectomy and closure of the fistula should be done.

regenerating hepatic cell of a blood supply by reducing portal flow and shunting arterial flow about the regenerating nodule, which lead to further hepatic cell anoxia and death. This concept of the progression of liver damage is a possible explanation of the progressive pattern of liver damage often exhibited by individuals with cirrhosis long after the primary cause of hepatic cell death has disappeared.

Much of our present-day therapy of cirrhosis is based on efforts to improve oxygenation of the liver cell by correction of anemia; to control hemorrhage and to reduce demands upon the liver through bed rest and control of intercurrent disease.

The next most common disease process that produces portal hypertension is occlusion of the portal vein prior to its entry into the liver, the so-called extrahepatic block. Although it accounts for perhaps only one of five cases in any over-all group, it is the most common cause for portal hypertension in children. The most common causes of extrahepatic block are cavernomatous transformation of the portal vein, spontaneous thrombosis associated with polycythemia vera, periphlebitis and thrombosis associated with omphalitis of the neonatal period, congenital atresia, inflammatory or neoplastic extrinsic pressure. The clinical manifestation of the venous block is similar to that of the intrahepatic block, i.e., dilatation of the collateral venous circuit, splenomegaly and occasional ascites; however, there is absence of liver damage.

The least common disease process that produces portal hypertension is occlusion of the outflow tract associated with constrictive pericarditis, inferior vena cava thrombosis and hepatic vein thrombosis (Chiari's disease). The first two levels of obstruction can be suspected if, in addition to portal hypertension, there is a coincident significant lower extremity venous pressure elevation. In the case of the latter, if there is evidence of rapidly developing portal hypertension and sudden tender enlargement of the liver associated with progressive failure, Chiari's syndrome must be considered.

Clinical Picture. In the early stages of portal hypertension the patient is often unaware of any abnormality, but occasionally he may note upper abdominal fullness associated with enlargement of the spleen, prominence of the anterior abdominal wall veins, particularly in the periumbilical region. More often than not, any symptoms that the patient may experience are over-

shadowed by symptoms related to the basic process which, as in the case of cirrhosis, may be weight loss, anorexia, fatigability and vague digestive difficulties. Even this is not constant and often the patient's presenting symptom is massive gastrointestinal hemorrhage.

Hints as to the etiology and duration of the disease process can occasionally be obtained from the history; however, more often than not these remain obscure. Nevertheless, it is of importance to establish, if possible, a history of chronic dietary inadequacies, alcoholism, infectious hepatitis, homologous serum jaundice, previous biliary tract disease or operation or contact with hepatotoxins. A previous history of jaundice or long-standing splenomegaly, with or without evidence of liver disease, is important. Two of the most common coincident diseases, peptic ulceration and diabetes mellitus, must be excluded by historical and laboratory evaluation.

On physical examination the findings that are of importance in establishing the diagnosis are jaundice, spider angiomas, abdominal wall collateral circulation, ascites, peripheral dependent edema and hepatosplenomegaly.

The immediate status of the individual can be rapidly assessed by the presence or absence of active bleeding and of shock. The extent of the underlying disease, if this is cirrhosis, can be roughly judged by the presence or absence of jaundice, new "crops" of spider angiomas, soft tissue wasting, ascites and, of most importance, liver tenderness.

Special and laboratory examinations are of great importance again in confirming the diagnosis of hypertension and in completing the etiologic picture. A thick barium swallow may demonstrate radiographically esophageal and gastric varices in perhaps seven out of ten individuals examined. Two of the remaining three will require esophagoscopy to demonstrate varices, and in the tenth and last individual varices will not be demonstrated.

Laboratory studies which reflect liver function are of major importance in determining the site and most likely cause of the block and in estimating, as in the case of cirrhosis, the degree of liver damage and, therefore, indirectly, the operative risk.

Differentiation between hepatic vein thrombosis (Chiari's syndrome) and intrahepatic venous block is difficult and depends on the nature of onset. The former evolves in a matter of days and is accompanied by

b Irreversible

Constrictive pericarditis
 Inferior vena cava obstruction
 Hepatic vein obstruction
 Intrahepatic portal obstruction
 Extrahepatic portal obstruction
 Extrahepatic portal arteriovenous fistula

Pathogenesis of Portal Hypertension. The surgeon is infrequently called to see a patient with hypertension arising from a normal physiologic response or from a completely reversible pathologic state. On the other hand, portal hypertension arising from an irreversible pathologic state is being brought more often to the attention of the surgeon because of his increasing capacity to correct some of its causes or results.

The anatomy of the blood supply to the liver is unique in that there are two afferent systems and one efferent system. As a result of the dual inflow tract, circulatory studies, summarized by Child, are unusually difficult to make and to interpret. Despite the complexities there is fair agreement of the estimates that approximately one-fourth of the minute cardiac output passes through the liver. One-third of this flow is delivered by the hepatic artery and two-thirds by the portal vein. Although portal vein blood has a lower oxygen content than hepatic artery blood, it does have an oxygen content higher than peripheral venous blood. This fact, coupled with the greater minute flow in the portal vein, makes the afferent venous system a significant source of oxygen which accounts for more than half of the oxygen supplied to the liver. If it were not for the numerous communicating channels within the substance of the liver between the two afferent systems and a more or less reciprocal flow relation between the two systems during periods of normal or abnormal stimulus, then intrahepatic or extrahepatic obstruction in the portal vein system would be of greater significance than it is. Whether permanent or temporary, partial or complete, occlusion of either portal vein or hepatic artery will usually lead to an increase in flow through the other vessel. However, this reciprocal relationship is usually insufficient to sustain complete integrity of the liver if either artery or vein is suddenly occluded. Any obstruction in the inflow or outflow tracts of the liver will lead to an elevated pressure within the afferent system. This seems to be of little consequence in the case of the hepatic artery; however, in the

portal system the changes are striking. When portal hypertension has developed gradually it is characteristic—to find splenomegaly, dilatation of the portal vein and of the existing collateral circuits between the coronary and azygos veins, between the falciform ligament and anterior abdominal wall, between portal radicles, retroperitoneal veins of Retzius and hemorrhoids. On the other hand, when sudden occlusion by thrombosis or by trauma has occurred in the hepatic vein or portal vein, engorgement of the entire portal vein or hepatic vein drainage bed is the outstanding feature in the early phase of the pathologic process (Popper). If the patient survives long enough, the collateral system will become significantly dilated.

The most common and clinically significant disease process that produces portal hypertension is cirrhosis, biliary or portal. In this instance, the obstruction to afferent portal flow occurs within the substance of the liver. At present, it is generally believed that hypertension is due to deformed intrahepatic vascular anatomy and that this deformity is caused by accelerated hepatic cell death followed by irregular and eccentric nodular regeneration of the parenchyma. The expanding regenerative parenchymal nodules of the cirrhotic liver obliterate or compress sinusoids and portal vein radicles. Other sinusoids, following death of liver cells, dilate and bring about ease of communication between hepatic arterioles and portal branches. After death of portions of a lobule and eccentric regeneration, the central (hepatic) vein comes to be situated near the periphery of the parenchymal nodule. Portal venous and hepatic arterial blood passing directly to this hepatic (central) vein thus by-passes much of the parenchyma in the central part of the nodule. The overall blood volume within the vessels of the liver diminishes. These vascular changes, summarized by Popper, are important in two respects because they set the stage for portal hypertension and for diversion of the blood supply from the regenerating hepatic cell.

Portal pressure elevation probably arises from three major factors: (1) the diminution in number of vessels assigned to carry a definite amount of blood, (2) the increase in resistance to flow in the remaining tortuous but intact venules. The vascular deformity deprives the

graphically small varices, whereas large and extensive varices may persist for years without incidence of rupture. On the other hand, the incidence of subsequent hemorrhage from varices following an initial episode is very high, suggesting that there are other factors still unknown that predispose the patient to repeated hemorrhage. It seems improbable that these factors can be assigned to chance alone. Occasionally, bleeding may occur following violent intra-abdominal or intrathoracic pressure changes associated with vomiting or coughing, but the cause is not usually so simple.

Bleeding may be the first indication of the presence of portal hypertension and the presenting symptom that brings the patient to the physician. The ultimate outcome of the hemorrhagic episode is frequently determined by early therapeutic measures. There is debate as to the therapeutic steps to take in the face of acute massive hemorrhage. Balloon tamponade of the esophageal varices and whole blood replacement are the important steps. Balloon tamponade techniques vary but take two general forms: (1) traction tamponade by a large inflated gastric balloon attached to a double-lumen tube snugged up into the cardia, thereby compressing the collateral vessels feeding the esophageal varices, (2) compression tamponade by a triple-lumen double-balloon tube which compresses the esophageal varices by inflation of the esophageal balloon. The first technique will control most hemorrhages as long as traction can be maintained and tolerated by the patient, but in most instances this technique must be supplemented by early ligation of the varices through transthoracic esophagotomy or through transabdominal gastrotomy. With the second technique, most hemorrhages can be controlled by compression of the esophageal varices by the balloon alone. If bleeding continues, this is indicative of a gastric varix or some other source of bleeding. In these rare cases, gastrotomy and ligation of the bleeding point are indicated. Of the two techniques, esophageal balloon tamponade is favored since it usually averts operative intervention at a time when operative stress can be seriously detrimental to the liver. This argument, of course, does not hold in the instance of portal hypertension secondary to a block in the portal vein, since in this instance the liver is normal. On the other hand, in practice, the esophageal balloon will control the hemorrhage and operation can be avoided. This may be of particu-

lar importance to a toddler who may have several years to achieve sufficient growth prior to a definitive shunting procedure. Esophagotomy and suture of varices afford only temporary protection from bleeding. This limited period of protection may be sufficient to prepare a poor-risk cirrhotic patient for operation, but it is insufficient to protect a toddler where years may be needed before a splenorenal shunt can be performed.

Constructive approaches to the long-term control of varices have taken two general forms: (1) decompression of the portal hypertension by a portal vein to vena cava or splenic vein to renal vein shunt (Fig. 14); (2) obliteration by interruption of the blood supply to the varices by ligating the varices. The latter has limited value since vascular connections are re-established usually within a relatively brief period of months. Partial esophagogastrectomy and a jejunal limb interposition enjoys a greater success but is limited in that associated postoperative nutritional problems may make it inadvisable in the individual with cirrhosis. This is a point yet to be established.

At this time the portacaval shunt in either the form of a splenorenal or a portal vein to vena cava shunt is generally accepted as the best available method of reducing portal hypertension. The portacaval shunt was introduced experimentally over seventy years ago, but only since 1943 has it been per-

crease the efficiency of this shunt.

Table 3 Differentiation between Intrahepatic and Extrahepatic Block

	INTRAHEPATIC BLOCK (CIRRHOSIS)	EXTRAHEPATIC BLOCK
Esophageal varices	Present	Present
Hepatomegaly	Usually present	Absent
Splenomegaly	Usually present	Present
Ascites	May be present	Rare
Peripheral edema	May be present	Absent
Thrombocytopenia	Usually present	Present
Leukopenia	May be present	Present
Anemia	Usually present	Absent
Jaundice	Usually absent	Absent
Liver function	Impaired	Not impaired

abdominal pain, progressive enlargement and tenderness of the liver, rapid production of ascites and, finally, varices with perhaps hemorrhage. On the other hand, in cirrhosis the progression of symptoms, although similar, is stretched out over months or years.

The differentiation between the extrahepatic and intrahepatic block is usually difficult (Table 3).

As previously mentioned, the presenting symptom of portal hypertension may be upper gastrointestinal hemorrhage, frequently severe. Practically speaking, if this occurs in a child with splenomegaly the statistics overwhelmingly favor a diagnosis of bleeding esophageal varices. Unfortunately, if little is known medically about the child prior to hemorrhage, splenomegaly may go undetected during the first few hours of hospitalization until blood volume is restored and the spleen re-expands to its pre-hemorrhagic size. In the adult, early differential diagnosis may be very difficult, but it is of great importance to attempt to make a differentiation since the two most common causes of massive hemorrhage, peptic ulcer and esophageal varices, require different therapeutic approaches. To complicate the differential diagnosis, it has been found that perhaps one out of every five adult individuals with cirrhosis and varices also has a peptic ulcer, and bleeding can occur from either. It is strongly urged that an esophageal balloon (Fig. 13) be passed as a diagnostic procedure during an acute hemorrhage in any individual in whom there is the slightest suspicion of underlying liver disease, even if there is a coincident history suggestive of peptic ulcer. If the balloon brings the hemorrhage under prompt control, the bleeding is probably from esophageal varices. If, on the other hand, bleeding is not brought under control, the source is usually gastric varices

Figure 13 Diagram of triple-lumen double-balloon tube used to tamponade esophageal varices. Note the method of connecting with a blood pressure manometer.

or an ulcer. In this latter instance, assuming that the individual is suspected of having cirrhosis, early gastrotomy is indicated.

Rarely, but sufficiently often to warrant mention, massive upper gastrointestinal bleeding can occur from hemorrhagic gastritis which may be an isolated phenomenon or part of a generalized bleeding diathesis associated with a terminal phase of cirrhosis.

Commonly we associate varices with massive sudden hemorrhage; however, they can seep blood slowly over periods of days or weeks and in these instances gastric neoplasms must be considered in the differential diagnoses.

Finally, but rarely, massive bleeding from a hiatus hernia must be differentiated from a bleeding esophageal varix. If bleeding occurs in the presence of both, differentiation and control come only by gastrotomy. Balloon tamponade is not effective in the presence of a hiatus hernia, in fact, it is contraindicated since it may impede blood flow in the midportion of the esophagus and fail to compress varices in the lower portion of the esophagus.

Treatment. Bleeding from esophageal varices is without predictability and may occur at any time during the disease process. There is no definite correlation between the cause of the hypertension and the time of onset, frequency or severity of bleeding. Neither does the size of the varices correlate with any of these. For example, massive fatal hemorrhage may occur from radio-

Figure 16. Anatomic relation of the portal vein to the vena cava as seen through a right thoracoabdominal incision. (From Madden: *Atlas of Techniques in Surgery*. 1958. New York, Appleton-Century-Crofts, Inc.)

slowly over a one- to two-year period, and that the procedure can be performed only in cases of prehepatic or intrahepatic obstruction. Furthermore, it has the theoretical disadvantage of disrupting part of the afferent flow into the liver.

Prognosis. Preparing an accurate statistical evaluation of the natural history of portal hypertension is a virtual impossibility. It is a rare condition and patients who reach the larger medical centers where statistical evaluation is possible have already undergone a certain amount of selection. It is a condition that is usually superimposed on a disease, cirrhosis of the liver, which exerts a dominant force on the evaluation of any therapeutic measure for portal hypertension. For example, portal hypertension may occur at any time in the cirrhotic process and may be associated with good or bad liver function; esophageal varices may appear at any time after portal hypertension has developed.

Every statistic has been recognized by the students in this field. In order to avoid broad comparisons of disease modifications which are, at best, laborious and frequently impossible, these statistical qualifications are seemingly ignored for a more simplified comparison of whether this or that form of tamponage stops acute hemorrhage, or this or that operation stops episodes of subsequent bleeding. Granting their inaccuracies, reported statistics do give some idea of magnitude. It is

Figure 17. Complete end-to-side portal vein to vena cava shunt (From Madden: *Atlas of Techniques in Surgery*. 1958. New York, Appleton-Century-Crofts, Inc.)

estimated that if supportive therapy alone is available, nearly all cases of extrahepatic and one-half of all cases of intrahepatic portal block will survive the initial major hemorrhage from varices. With the addition of esophageal tamponage, three-quarters of the intrahepatic group will survive the initial hemorrhage. Without additional treatment, one-half of the patients who survive the initial hemorrhage will live five years or more without additional hemorrhage. Additional therapy in the form of a technically satisfactory end-to-side portal vein to vena cava shunt will result in only one in forty patients dying as a result of operation and one in twenty having a subsequent hemorrhage. These recent statistics represent a marked improvement over the past, but five years will be needed to determine alteration in longevity.

TUMORS OF THE LIVER

Differential diagnosis of benign, primary malignant and metastatic tumors of the liver is usually resolved only by biopsy. Clinical manifestations are not characteristic and include increasing anemia, sensation of fullness in the hypochondrium, weight loss and occasionally fever when a rapidly growing neoplasm undergoes central ischemic necrosis. Late stigmata of progressive invasion and compression of bile ducts and blood vessels include obstructive jaundice and signs of progressive cirrhosis with enlarging liver, ascites and abdominal pain.

Benign Tumors. Benign tumors of the liver are generally pathologic curiosities, rarely diagnosed, and are usually encountered at autopsy or operation for other disease. Lipoma, fibroma, adenoma, hamartoma

Figure 15 A completed end-to-side splenorenal shunt (From Madden Atlas of Technics in Surgery 1958 New York, Appleton-Century-Crofts, Inc.)

formed in the human with any significant frequency. Since then the operative technique and the preoperative and postoperative management of the patient have undergone considerable refinement and deserve brief summaries.

Patient selection. Recommendation for operation depends on evidence of portal hypertension (varices, splenomegaly, abdominal wall collateral circulation, ascites), a history of active upper gastrointestinal tract bleeding when causes other than varices have been excluded, and a demonstration on the part of the patient that liver function can be improved with a conservative medical regimen. In the latter point, some elaboration is indicated. In the past, considerable importance has been placed on tests of liver function as a basis for patient selection. Although this is still valid to a degree, selection on the basis of an individual's capacity to improve liver function during a period of conservative medical therapy seems to be of greater value and serves as a method of estimating reserve liver capacity. If a patient shows continued deterioration of liver function despite conservative therapy, the end is near and operation will only serve to hasten it. A word of caution should be sounded, however, in any instance following a period of massive gastrointestinal tract hemorrhage. liver function studies can be noted to be progressively depressed despite a good medical regimen. This depression, frequently transient, discourages any emergency operation. It clears in three to four weeks after the hemorrhage and does not carry the same

ominous note as a similar pattern of deterioration in a patient who has not recently bled.

The preoperative and postoperative care of these patients is essentially the same as in the accepted medical regimen of cirrhosis, i.e., bed rest, nutritious diet rich in calories, proteins and vitamins, correction of ascites, if present, by salt restriction, diuretics and paracentesis, and correction of anemia by whole blood transfusion. Recently, by virtue of recognition, the problem of "ammonia intoxication" has been seen more often. Occasionally this is evident preoperatively, but more frequently, postoperatively. The syndrome of ammonia intoxication is presently believed to be a result of an abnormal accumulation of ammonia in the body, occurring when the liver is unable to utilize ammonia in the ornithine cycle, when there is shunting of portal blood around the liver, and, finally, when there is greater production of ammonia from high protein diets. Usually transient, occasionally chronic, the syndrome can be controlled by reducing the protein in the diet or by reducing the capacity of bacteria to produce ammonia. Of the two methods, the latter is preferable and can be accomplished by giving small amounts of neomycin and bacitracin orally.

Surgical procedure. Practically speaking, the portal and splenic veins are the only two veins in the portal system of sufficient size to warrant use in a shunting procedure. Rarely, the superior mesenteric can be used. The use of each vein has certain individual advantages and disadvantages. In splenorenal shunt (Fig 15), in which the splenic vein is anastomosed end to side to the renal vein, the actual and theoretical advantages are immediate control of hypersplenism by virtue of splenectomy and less distortion of the afferent blood flow to the liver. The disadvantages are that a technically satisfactory shunt can be difficult to achieve. Portal pressure reductions are usually not as great as those achieved by the portal vein to vena cava shunts and follow-up studies would suggest a higher incidence of closure of the shunt. In portal vein to vena cava shunt (Figs. 16 and 17), in which the portal vein is anastomosed end-to-side to the vena cava, the actual advantages are usually satisfactory reductions in portal pressure by a shunt which is technically easier to achieve and an extremely small incidence of shunt closure, as suggested by follow-up studies. The disadvantages are that hypersplenism is not improved immediately, but improves

will arouse the suspicion of the surgeon, but a definite diagnosis cannot be made unless biopsy of the liver is performed during surgical exploration or through a needle. The needle biopsy technique may obviate the necessity of a surgical exploration if the specimen is positive for tumor cells. However, a negative report does not exclude the possibility of metastatic liver disease.

The clinical significance of suspected metastatic disease in the liver on physical examination, or of documented disease in the liver on biopsy, is that it presents, in our present state of cancer therapy, a point of no return as far as curative resection of the primary lesion is concerned. Even though this represents a convenient clinical rule, the occasional patient in whom a solitary neoplastic focus or local direct invasion can be removed in an en bloc resection should not be overlooked.

One of the most striking features of metastatic liver disease is the frequent advanced degree of liver destruction unassociated with real clinical evidence to suggest liver function impairment.

PYOGENIC ABSCESS OF THE LIVER

The advent and subsequent widespread use of antibiotics have decreased the incidence of pyogenic abscess of the liver. This now rare and subtle disease process, however, should remain an important diagnostic consideration for the clinician can often prevent an otherwise fatal outcome by early recognition and treatment.

Pathogenesis. Frequently bacteria reach the liver via the portal vein, the hepatic artery and the lymphatic system. In the normal individual, these microorganisms are destroyed by the liver. Occasionally, however, this protective mechanism may be impaired by primary liver disease or by overwhelming generalized septicemia, which can disrupt the favorable balance normally existing between pathogenic bacteria and host resistance. This imbalance can be directly reflected in the formation of solitary or, more commonly, multiple liver abscesses.

Although liver abscesses can follow septicemia from any primary focus, they are most commonly a sequela of primary intraperitoneal infections, particularly those which have venous drainage via the portal system. Direct extension into the liver can occur from suppurative disease in the gallbladder and in the subphrenic space and from peptic ulcer penetration. The sequence of acute appendicitis with cellulitis of the

mesoappendix and mesentery, pylephlebitis and septic emboli to the liver is the recognized common primary mechanism; however, in over half of the collected cases there has been no recognized primary focus of infection.

Liver abscesses secondary to infection arising primarily from the gastrointestinal tract will usually yield cultures of *Escherichia coli*, nonhemolytic streptococcus or *Clostridium perfringens*. Those arising from primary infection elsewhere will usually yield cultures of *Staphylococcus pyogenes* var. *aureus* or hemolytic streptococcus. Many other organisms have on rare occasion been found in liver abscesses; they include gonococci, spirochetes, *Klebsiella pneumoniae* and *Salmonella typhi*.

Symptoms. The symptoms of pyogenic abscess of the liver are usually subtle in the beginning, develop insidiously and can become masked by the symptoms arising from the primary focus of infection. When masking has not occurred, malaise, anorexia and low-grade fever associated with vague right upper quadrant pain may be the only suggestive symptoms at the onset. With progression of the disease, the syndrome will change to a general toxicity reaction of spiking temperature, in the 105° to 106° range, associated with shaking chills, profuse sweating and the local manifestations of severe right upper quadrant pain with frequent radiation to the right shoulder and hypochondrium.

Local signs depend in part upon which portion of the liver has undergone abscess formation. Direct shock tenderness over the lower rib cage and tenderness by palpation of an enlarged liver are usually constant findings. A variable amount of clinical and laboratory icterus may be present, progressive jaundice is a poor prognostic sign. Increase in the number of leukocytes to 20,000 to 25,000, with a predominant polymorphonuclear shift, is common and can be used as a differential point in ruling out the possibility of an amebic abscess. Elevation of the right diaphragm, as seen on fluoroscopic examination, is an occasional finding in abscesses of the right lobe. Also associated with right lobe expansion can be compression of the inferior vena cava, measurable as an increase in femoral vein pressure.

Treatment. The principles of therapy are the same as those of therapy of pyogenic abscess elsewhere. Incision and drainage must be first accomplished. An appropriate antibiotic proved to be effective against the

and myoma have been reported, but the most common is cavernous hemangioma. Varying greatly in size, these tumors usually present beneath the liver capsule as purple, raised, multinodular, compressible masses. Except for large hemangiomas, which may be ruptured by trauma, excision is usually unnecessary since progressive enlargement is the exception.

Malignant Tumors. Primary carcinomas of the liver are rare, have a geographical incidence which parallels that of cirrhosis of the liver and comprise up to 0.3 per cent of all autopsy findings and up to 2.5 per cent of all cancers. Up to 1955, approximately 2500 histologically proved cases had been recorded in the world literature. Two peak periods of age incidence occur in infancy and childhood and in the fifth and sixth decades, the tumors in the former period frequently being of the embryonal type with organoid features and those in the latter of the parenchymal hepatic cell type. A third histologic type is derived from intrahepatic bile duct cells and is occasionally associated with hepatoma cells as a mixed tumor. Predominance of involvement of males and of patients with cirrhosis has been well documented.

In the Department of Surgical Pathology at Columbia-Presbyterian Medical Center in New York, twenty-one patients with proved primary liver carcinoma were seen from 1930 to 1955. In the Babies Hospital in New York, from 1922 to 1955, seven patients were observed.

The etiologic basis of liver carcinoma is at present unknown, but the relationship to cirrhosis, with fibrosis and regeneration of new liver cells, is receiving special attention. The gross pathologic process varies from single, large, irregular and nodular masses to multicentric nodules involving the entire liver. A third, less common, scirrhous form has also been observed. The tumors are usually deep seated and do not present the umbilicated superficial masses seen with metastatic lesions to the liver.

Clinically there is little to support differential diagnosis between cell types, though liver cell carcinoma is generally the most rapidly progressive. Extrahepatic metastasis occurs in all parts of the body, the most frequent sites being the lung, lymph nodes and hepatic vein. Survival with either type beyond one year after diagnosis has been made by laparotomy or punch biopsy is a rarity.

At the present time, radical partial hep-

ectomy offers the only hope of cure. Resection of the gross tumor and surrounding liver appears to prolong life in some patients and several cures have been reported. The operative mortality is high, up to 25 per cent, and survival from one and one-half to seven years has been reported in 42.2 per cent of forty-five patients. Of the twenty-eight patients seen at the Columbia-Presbyterian Medical Center, only one has survived; this patient had partial hepatectomy at the age of thirteen years and has been well for six years. Isolated case reports continue to appear, but few patients survive for five years following operation. With progress in earlier detection and technical facility, these results can only improve.

Metastatic carcinoma of the liver is as common a finding in the family of neoplastic disease as primary carcinoma is rare. The reason for this is twofold. One, the liver filters the blood and lymph return from an organ complex which has a high intrinsic incidence of neoplastic disease and, two, the liver provides a superb medium in which a tumor embolus will grow. Consequently, liver metastases from malignant tumors arising from the gastrointestinal tract, the extrahepatic biliary tract and the pancreas are common. The routes of spread are essentially three in number.

Tumor emboli gain access to the portal

portal system by tumors arising in, for instance, the genitourinary system. Tumor emboli which gain access to the liver via the hepatic artery are frequently derived from metastatic or primary malignant tumors in the lung.

Tumor cell transport via the portal lymphatics in a pure state is rare. However, the combination of venous and lymphatic transport is common.

Tumor cell invasion by direct extension into the liver is uncommon since the capsule of the liver seems to offer an effective barrier. Even though this mode of spread is rare, collective evidence suggests that direct invasion when seen is usually from neoplasms arising in the gallbladder or stomach and rarely from the kidney, adrenal gland, colon, esophagus or pancreas.

The diagnosis of a metastatic tumor in the liver must be suspected in every patient under investigation for malignant disease elsewhere in the body. An enlarged liver, with or without one or more firm masses,

ated fluid, may occur. Leukocytosis is usually minimal and the percentage of polymorphonuclear cells rarely exceeds 60. Liver function tests rarely show significant alteration.

Treatment. The major objectives are decompression of the abscess cavity, prevention of local bacterial invasion and riddance of viable amebas from the individual as a whole.

The drug of choice in amebic hepatitis and amebic liver abscess is chloroquine, in recommended dosages of 0.6 gm. by mouth daily for two days, followed by 0.3 gm. daily for two to three weeks.

Abscess cavity decompression should be accomplished by trocar puncture and aspiration. Great care should be exercised to introduce the trocar through the extraperitoneal subdiaphragmatic route and to prevent any bacterial contamination. If it seems justified, the cavity may be irrigated with a suitable broad-spectrum antibiotic and chloroquine.

Finally, the primary infection must be treated by a course of any of the accepted antamebic chemotherapeutic agents of which Diiodoquin is perhaps most common. Properly treated amebic hepatitis and hepatic abscess have, on the whole, a good prognosis.

bacteria on in vitro culture is then administered systemically and locally into the abscess cavity.

Incision and drainage should be carried out in the solitary, but not the multiple, abscess group, for adequate drainage of the latter can seldom be achieved and in any such extensive attempt at hepatic drainage the danger of hemorrhage would be formidable. The course of the incision and subsequent drainage tract should never traverse the free pleural or peritoneal cavities, because of possible spread of the infection into these free spaces. If the abscess cannot be drained via the infradiaphragmatic retroperitoneal route, the operative procedure should be staged, during the first stage the peritoneal or pleural avenue of communication is obliterated either by suture or packing, at the second stage, following inflammatory walling off of the area, the abscess is entered and drained. Diagnostic needle aspiration should be reserved for exploration under direct vision at the time of operation. Percutaneous needle aspiration should be avoided because of uncontrolled pleural or peritoneal contamination and should be reserved for the rare cutaneous pointing of an abscess.

AMEBIC ABSCESS OF THE LIVER

Amoebiasis is recognized as a common disease in the Tropics and a less common, but nevertheless significant, disease in the Temperate Zone. Since its identification by Losch in 1875, studies have established the probable incidence in the United States as 10 per cent of the population. This figure, probably high for the northern sections of the country and low for the southern areas, establishes an incidence which makes the disease of local importance.

The frequency with which amebic abscess of the liver occurs following primary colon infestation is unknown, however, in 1945, Payne reported a greater than 50 per cent incidence of hepatitis and a 3 per cent incidence of hepatic abscess in 1000 patients with amoebiasis. Amebic abscess has an unexplained predilection for young male adults.

Pathogenesis. *Entamoeba histolytica* traverses the upper gastrointestinal tract following ingestion in the cystic form. In the distal small bowel, the ameba will emerge from the cyst form and, following division, arrive in the cecum as the invasive metacystic trophozoite. During the invasion of the colon wall the venous branches may be invaded and the trophozoite will be transported to

the liver through the portal system. There, the described pathologic process is that of thrombotic occlusion of the smaller venules by fibrin-enmeshed amebas. Subsequent ischemia of the vein wall, plus the proteolytic enzyme elaborated by the ameba, will destroy the vein wall and give the ameba free access to invade and destroy the liver lobule. Thus early and frequently multifocal invasion of the liver gives rise to the clinical diagnosis of amebic hepatitis. With further invasion and proliferation of the intrahepatic colonies, focal areas of complete necrosis will form and give rise to the liver abscess. The abscess is usually located in the dome of the right lobe, probably as a result of the predominance of right colon blood return to the right lobe and the usual infestation of the cecum and ascending colon. The abscess wall thickness usually represents the rapidity of destruction, with the thicker, more fibrous wall confining the slower destructive process. The abscess cavity is filled with a semifluid material made up usually of cellular debris and old blood. In the large abscesses, free floating amebas are rare and a positive diagnosis must be obtained from wall scrapings. In the smaller cavities, amebas can frequently be seen in the "chocolate pus." Cultures for bacteria are usually negative.

The natural course of an abscess, if allowed to progress untreated, is expansion, destruction and rupture into the adjacent anatomic areas. Invasion through the diaphragm into the lung, with occasional subsequent evacuation through a bronchus, is a common complication.

Symptoms. As previously indicated, the acute hepatitis stage, if uninterrupted by therapy, may merge imperceptibly into the abscess formation, and, as expected, there are symptoms common to both.

The patient usually complains of anorexia, malaise, weakness and a progression of right upper quadrant discomfort ranging from vague heaviness to severe pain. The pain may radiate to the shoulder, but this is not a prominent feature. There may be no previous history of dysentery.

Weight loss, fever and profuse sweating are common early findings. Jaundice is infrequent. The liver may be slightly enlarged and slightly tender on pressure. Perhaps one of the most important findings is that of an elevated diaphragm with either reduced mobility or fixation. This may be associated with an actual bulge if an abscess is present. Localized pleurisy, with or without associ-

Two ductal systems usually lead the external secretion of the pancreas to the duodenum, although variations are frequent. The major duct, or duct of Wirsung, courses through the tail and body, neck and part of the head of the gland to enter the duodenum at the ampulla of Vater in close connection with the orifice of the common bile duct. The major pancreatic duct and the bile duct join and share a common opening into the duodenum in approximately 70 per cent of human beings. In many of these the two lumens are separated by a septum to within a few millimeters of the common opening. In other individuals the openings are separate, although close together. The minor pancreatic duct, the duct of Santorini, arises in the head of the pancreas and usually enters the duodenum separately proximal to the ampulla of Vater. Variations in the minor duct are common, it may connect freely with the duct of Wirsung within the pancreas, it may be absent or it may be of such prominence that it appears to be draining most of the pancreatic juice. The distal part of the common bile duct may lie between the pancreas and duodenum, or actually may pass through a portion of the head of the pancreas. In any case, it is so closely applied to the pancreas that tumors and

occasionally inflammation of this portion of the gland may block it and cause obstructive jaundice.

Microscopically, the pancreas consists of glandular alveoli distributed in a racemose fashion about ductules. The islets of Langerhans are scattered throughout; they occur in greater concentration in the body and tail of the pancreas, which probably accounts for the fact that about 75 per cent of islet cell tumors are in this region.

The pancreas is both an exocrine and an endocrine gland. Its exocrine secretion, pancreatic juice, enters the duodenum via the pancreatic ducts and provides enzymes for digestion of foodstuffs as well as alkali to aid in neutralization of acid chyme. Its best-known internal secretion, insulin, is important in the regulation of carbohydrate metabolism.

Pancreatic juice is a colorless, odorless, alkaline fluid with a pH of 8.0 to 8.3. Its specific gravity varies between 1.007 and 1.012, being increased after stimulation that results in secretion of juice containing nitrogen and, hence, protein and enzymes in great concentration. It is decreased after stimulation that results in juice containing little nitrogen. Its alkalinity is due to its content of large amounts of bicarbonate, the

Figure 1. Anatomy of the pancreas, relating to surrounding structures (Walters, W., and Clagett, O. T.: *Surgery of the Pancreas*. In Piersol, G. M. *The Cyclopedia of Medicine, Surgery and Specialties*, vol. 10. W. B. Saunders Co.).

THE PANCREAS

By JOHN M. WAUGH, M.D., and
GEORGE A. HALLENBECK, M.D.

JOHN McMASTER WAUGH, the son of a doctor, is a Missourian who went from Tarkio College, situated in the city of his birth, to Rush Medical College. He received his surgical training at the Mayo Clinic, where he remained to become the Chief of a surgical section

GEORGE AARON HALLENBECK, also the son of a physician, returned to his birth place after receiving his liberal arts and medical education at Northwestern University. He chose to do graduate work in physiology to prepare himself for his surgical training

The pancreas is an elongated gland situated retroperitoneally and lying transversely behind the stomach. Its length varies from 12.5 to 15 cm, its breadth from 3.4 to 4 cm and its thickness from 1.5 to 2.5 cm. Its weight ranges from 70 to 115 gm. For descriptive purposes, it can be divided into three parts, namely, the head, the neck, and the body and tail. The head conforms to the concavity formed by the duodenum, with which it is in contact. The neck is a slight narrowing of the gland where it lies anterior to the superior mesenteric vessels. The body tapers toward the left to form the tail.

The relationship of the pancreas to surrounding structures is clearly shown in Figure 1. When the abdomen is first opened, the pancreas is hidden from view by the stomach and the transverse colon and mesocolon. It can be exposed by division of the gastrocolic omentum followed by retraction of the transverse colon downward and retraction of the stomach upward. The neck, together with part of the body and head of the pancreas, also can be exposed by division

of the gastrohepatic omentum and retraction of the stomach downward. The tail of the pancreas touches, or nearly touches, the spleen in a sufficient number of instances that care must be taken to avoid injuring it during splenectomy.

The space bounded by the pancreas posteriorly, the gastrohepatic omentum, stomach and gastrocolic omentum anteriorly and the transverse colon and mesocolon inferiorly is the omental bursa, or lesser peritoneal cavity. It communicates normally with the greater peritoneal cavity by the foramen of Winslow, which lies behind the portal vein, common bile duct and hepatic artery. Arterial blood is supplied to the pancreas by branches from the vascular anastomosis of the superior pancreaticoduodenal artery from above and the inferior pancreaticoduodenal artery from below. The latter courses between the head of the pancreas and the duodenum and branches from the splenic artery, which courses from right to left along the superior border of the body and tail of the gland.

Circumstantial evidence suggests that it may be formed by alpha cells in islets of Langerhans. It has been theorized that the reason for the surprisingly low requirement for insulin after pancreatectomy is that the hyperglycemic factor, glucagon, has been eliminated along with endogenous insulin.

Dogs maintained by use of insulin after pancreatectomy do poorly and show fatty infiltration of the liver. This disorder of the metabolism of fats is prevented by the feeding of raw pancreas and, to some extent at least, by feeding pancreatic juice or such lipotropic agents as choline and methionine. Although controversy exists as to the mechanism involved and the importance of the postulated pancreatic hormone (lipocaic) in this regard, it is clear that the pancreas in some way participates in regulation of the metabolism of fat. Evidence has not yet been found that a similar fatty infiltration of the liver develops in human beings after pancreatectomy.

ANOMALIES OF THE PANCREAS

Annular Pancreas. The ventral anlage of the pancreas on rare occasions fails to fuse with the larger dorsal anlage. It then develops independently and comes to surround the second portion of the duodenum as a circular and, sometimes, constricting ring. This abnormally placed pancreatic tissue has been reported to be the site of pancreatitis and to cause obstruction of the common bile duct, but the most frequent way in which it produces symptoms is by causing obstruction of the duodenum. Duodenal obstruction may be evident in the first days of life, but, more commonly, patients with this disorder reach adult life before requiring treatment. The lesion appears to be asymptomatic in many persons. Obstruction of the duodenum can be corrected easily in some patients by careful division of the constricting ring through its lateral side, followed by suture of the cut surfaces of ectopic pancreas. In other patients, the condition can be better treated by gastroenterostomy or duodenojejunostomy. Of these last two operations, duodenojejunostomy performed retrocolically probably is preferable because it is more likely to avoid the complication of peptic stomal ulceration, which can follow gastroenterostomy, and because it should provide better drainage of the proximal portion of the duodenum while not interfering with the function of the stomach.

Pancreatic Heterotopia. This is the presence of pancreatic tissue outside its usual

Figure 2. Nodule of heterotopic pancreatic tissue, measuring 1.5 by 1 by 0.8 cm. in the anterior wall of duodenum immediately below the pylorus. The mass looked like a fibroma grossly at operation (Waugh, J. M.: *Surgical Diseases of the Pancreas*. In Walters, W.: *Lewis' Practice of Surgery*, vol. 7. W. F. Prior Co.).

location and without continuity with the pancreas proper. A total of 471 instances had been reported in the literature up to 1944. Heterotopic pancreatic tissue may occur in the walls of the duodenum (Fig. 2), stomach or jejunum; less frequently it is seen in the gallbladder, splenic capsule or ileum or in Meckel's diverticulum. The tissue usually presents itself as a single, firm, yellow or white, opaque, lobulated, round or irregular node with a granular surface. Typically, this misplaced tissue may range from 1 cm. to 4 cm. in diameter. Vague digestive symptoms, or symptoms suggestive of gastric or duodenal ulcer or of cholecystic disease, may be associated with heterotopic pancreatic tissue and apparently have often been relieved by removal of the tissue.

TRAUMATIC LESIONS OF THE PANCREAS AND PANCREATIC FISTULAE

Injuries of the Pancreas. The pancreas is injured but rarely because of its anatomic situation. It is protected posteriorly by the spinal column, the lower ribs offer it a certain degree of shelter anteriorly and it is shielded by the stomach and other viscera. Trauma severe enough to injure the pancreas usually produces injury to other organs of

exact concentration of which depends on the rate at which juice is being secreted. The sum of the concentrations of chloride and bicarbonate ions is constant and nearly the same as the total base in plasma. At extremely decreased rates of secretion the bicarbonate may exist in the same concentrations that it does in plasma, whereas it may reach more than 140 mEq per liter at faster rates of secretion. Sodium and potassium occur in concentrations equivalent to those in plasma. The juice contains a considerable amount of protein, with which the enzymes are associated.

Pancreatic juice contains proteolytic, amylolytic and lipolytic enzymes. Trypsin, probably a combination of two or more enzymes, is secreted in the inactive form of trypsinogen, which is activated by contact with enterokinase found in the small intestine. This trypsin group of enzymes can reduce proteins to peptides. Pancreatic lipase splits fats to glycerin and fatty acids in the presence of bile salts furnished by the liver. Pancreatic amylase splits carbohydrates to maltose. The optimal pH for activity of all three enzymes is more than 7.0. As little as 10 per cent of the normal quantity of pancreatic juice suffices to permit normal digestion and absorption of food. Complete removal of the gland in dogs and man is usually, but inexplicably not always, followed by impaired digestion and absorption, particularly of fat and protein. The reason for the lack of this deficit in some patients after pancreatectomy is not understood. Steatorrhea resulting from deficiency of pancreatic juice often can be controlled by oral administration of pancreatic extracts (pancreatin).

Pancreatic juice also contributes to the neutralization of chyme entering the duodenum from the stomach, sharing this function with bile and succus entericus. This is of great importance for two reasons: the enzymes in intestinal and pancreatic juice function best in an alkaline environment and peptic ulceration of the duodenum, a likelihood when such neutralization is prevented, is controlled if neutralization is effective.

Experiments carried out principally on dogs indicate that secretion of pancreatic juice can be stimulated by sham feeding (cephalic phase) and by the presence of foodstuffs or acid in the intestine (intestinal phase). A gastric phase of pancreatic secretion has not been demonstrated, that is, food limited to the stomach does not stimulate pancreatic secretion. Vagotomy abolishes the

cephalic phase of pancreatic secretion as it does the same mechanism for gastric secretion. Pancreatic juice secreted in response to sham feeding or stimulation of the vagus nerves is sparse, viscous and rich in enzymes. Acid placed in the duodenum calls forth profuse secretion of pancreatic juice which is relatively poor in enzymes but of considerable volume; it contains bicarbonate in great concentration.

In 1902, Bayliss and Starling extracted a substance from the mucosa of the small intestine which, when given intravenously, stimulated secretion of watery pancreatic juice poor in enzymes. This was the first known hormone and was named secretin. The validity of the concept that it is a hormone has been amply proved since. One adequate stimulus for release of secretin is a decrease of the pH of duodenal contents. In the dog, the pH must reach 4.0 before a very active response is obtained. Products of digestion of protein, fats, fatty acids and soaps, when introduced into the small intestine, stimulate flow of a pancreatic juice rich in enzymes. Products of digestion of carbohydrate are less active in this regard.

In 1943, Harper and Raper isolated from duodenal mucosa a second substance, which they named *pancreozymin*. This calls forth the secretion of pancreatic juice rich in enzymes when it is given intravenously. Evidence now favors the concept that *pancreozymin* is important in the pancreatic secretory response to food. The presence or relative importance of nervous reflexes between the small intestine and pancreas in stimulation of pancreatic secretion by food cannot be assessed with certainty at present.

Total pancreatectomy is followed by fatal diabetes unless insulin is given. The relationship between the pancreas, the adrenal cortex and the anterior pituitary gland in the regulation of carbohydrate metabolism and in spontaneously occurring diabetes is of great importance. Suffice it to say that insulin, formed by the beta cells in the islets of Langerhans in the pancreas, controls the hyperglycemia of ordinary diabetes and of the diabetes which follows pancreatectomy. Paradoxically, as little as 15 to 30 units of insulin daily usually controls the diabetes after pancreatectomy in man. These quantities are much less than those often required to control spontaneously occurring diabetes. A hyperglycemic glycogenolytic factor called glucagon also can be extracted from pancreatic tissue. Its status as a hormone and its physiologic importance remain uncertain.

plied equally to the pancreatic duct in a way that should eliminate any differential pressure between the two systems. Recent evidence indicates that bile in the canine pancreatic duct at physiologic pressures does not cause pancreatitis. Obstruction of the pancreatic duct in fasted animals produces edema of the pancreas and prompt increase in values for serum amylase but does not produce the severe pancreatitis seen clinically.

If dogs are fed shortly before the pancreatic ducts are ligated, severe pancreatitis usually develops. Obstruction of the flow of pancreatic juice in the presence of an actively secreting gland apparently can cause pancreatitis. Although ligation of pancreatic arteries or veins alone does not cause acute pancreatitis, such alteration of the pancreatic blood vessels, when combined with obstruction to pancreatic ducts, results in severer acute pancreatitis than that caused by obstruction of the ducts alone. It seems likely that vascular factors can be important in the progression of acute pancreatitis. Cases of pancreatitis occurring in the presence of obstruction of a common channel by a stone at the ampulla of Vater have been reported, but absence of such obvious mechanical obstruction is commoner. Edema and spasm of the sphincter of Oddi have been postulated. Ample evidence in human beings and in dogs shows that such spasm can occur in response to a variety of drugs. Alcohol, commonly linked with pancreatitis in clinical cases, is especially active in this regard.

Once the disease is established, pancreatic enzymes often exude from the gland into the peritoneal cavity. Lipase hydrolyzes near-by fat, producing necrosis of the fat, which is grossly visible as whitish spots consisting of salts of fatty acids.

Acute edematous pancreatitis. This form of acute pancreatitis typically is manifested as an attack of severe epigastric pain usually referred through to the back and often felt in the scapular regions and lower part of the thorax. As already mentioned, many of these patients have gallstones as well and previously may have experienced the indigestion and colic characteristic of this disorder. Jaundice, if it occurs, is usually transient and seldom severe. Nausea and vomiting are common and epigastric tenderness is virtually always present. Leukocytosis and a moderate degree of fever occur. Shock, a typical feature of acute hemorrhagic pancreatitis, is not seen in the acute edematous variety of the disease. Although penetrating

duodenal or gastric ulcer and coronary occlusion are differential diagnoses in this condition, which so often accompanies it, is usually the most pressing problem.

The presence of acute pancreatitis must be suspected in any patient who has sudden onset of epigastric pain, often suggestive of biliary colic or acute cholecystitis, which persists for more than twenty-four hours. The presence of this type of pancreatitis formerly became known with certainty only after the swollen, tense pancreas and, often, regions of necrosis of fat were seen at laparotomy. Now the presence or absence of acute pancreatitis can be learned with considerable certainty by a determination of serum amylase, the value for which will be increased when the disease is present. The activity of serum lipase requires longer to measure, increases more slowly but remains increased longer than does the activity of serum amylase. Measurement of serum amylase is an extremely important test that can be done quickly and should be performed whenever acute pancreatitis enters the differential diagnosis. The test is not absolutely specific. Moderately elevated values can occur, for example, with acutely perforated duodenal ulcer.

Surgical treatment has been tried during the acute phase of edematous pancreatitis. It usually has consisted of procedures such as cholecystostomy, cholecystectomy and perhaps drainage of the common bile duct and the placing of drains in the region of the pancreas. Data indicate that a much lower mortality rate is obtained by avoiding laparotomy at this stage of the disease and planning later study of the biliary tract, with subsequent surgical correction of such lesions as cholelithiasis, choledocholithiasis and cholecystitis after the acute process subsides. Thus, current opinion favors medical treatment of acute edematous pancreatitis, a fact that renders accurate diagnosis doubly important.

Specific measures that have been found useful include: (1) For relief of pain, the use of nitroglycerin in a dose of $\frac{1}{100}$ or $\frac{1}{150}$ gram is worth a trial. However, opiates are usually needed. Bilateral blocking of the splanchnic nerves with procaine hydrochloride is recommended by some physicians, both to relieve pain and in the hope that somehow it will relieve the spasm in the ducts and blood vessels which they assume to occur. (2) Nothing is given by

such severity as to endanger the patient's life. A number of penetrating wounds, caused chiefly by gunshot or stabbing, have been reported. The pancreas can be injured by nonpenetrating wounds such as those caused in auto accidents by compression against the steering wheel. In several of these victims, the pancreas has been sutured and recoveries have been reported. It is seldom that injuries can be diagnosed with certainty by symptoms manifested by the patient. Evidence of shock or intra-abdominal hemorrhage is the usual indication for abdominal exploration in these patients. In an exploration of the upper portion of the abdomen after any type of injury, one always should ascertain that the retroperitoneal portion of the duodenum and the pancreas have not been injured. After suture of the gland, drains should be left to allow escape of the pancreatic fluid from the injured region.

If the main duct has been severed, it may be possible to reconstruct it over a T tube, the adjacent tissue being approximated around the T tube, with interrupted silk sutures. The T tube should be left in place for about three weeks. In some instances of injury to the body and tail of the pancreas, resection of this part of the gland will offer the safest solution to the problem.

Pancreatic Fistulae. Most pancreatic fistulae follow the drainage of pseudocysts, stab wounds or gunshot wounds of the upper part of the abdomen or surgical trauma to the pancreas. Partial pancreatic fistulae generally close spontaneously, although this may require months. Conservative measures should be tried unless the patient is losing an alarming amount of pancreatic juice. The juice often can be collected by a catheter placed into the fistulous tract and attached to a bottle or a rubber bag. Once the fistula is well established, the pancreatic juice often becomes clear and sufficiently inoffensive so that the patient can drink it, thus avoiding the sequelae of constant loss of fluid and electrolytes. Surgical treatment occasionally becomes necessary when conservative methods fail. If the fistula is from the tail or body, this portion of the pancreas can be removed readily. This is the simplest way of correcting the fistula. On the other hand, if there is an excessive inflammatory reaction about the fistula, or if the latter is in the region of the head of the pancreas, internal drainage, such as to the duodenum or jejunum, usually proves satisfactory.

INFLAMMATION OF THE PANCREAS

Acute Pancreatitis. Acute pancreatitis, apart from the specific type which may occur with mumps, may be divided into two varieties, namely, acute edematous pancreatitis and acute hemorrhagic pancreatitis. The latter and less common type is a fulminating process which frequently progresses rapidly to necrosis of the pancreas and death of the patient. The former and more common variety often is accompanied by cholecystic disease and has a lower mortality rate. Acute pancreatitis has been observed at all ages from two to seventy-seven years, although most patients are between thirty and fifty years of age. As a rule, it occurs spontaneously but it can follow trauma to the abdomen or surgical operations, usually those in which dissection was performed in the region of the pancreas.

Factors suggested as possible causes of acute pancreatitis are numerous and include infection, obstruction of the pancreatic duct, chemical irritation due to reflux of bile or duodenal contents into the pancreatic ductal system, autolysis due to activation and escape of enzymes into the gland, local vascular disturbances and allergic phenomena. At present, it is fair to state that the exact cause of pancreatitis is not known. The commonest theories predicate obstruction of the pancreatic duct and passage of bile into the ductal system. Usually the major pancreatic duct and the common bile duct join shortly before they enter the duodenum and share a common channel of variable length. On anatomic grounds, edema, spasm or the presence of a small stone at the papilla of Vater could obstruct both ducts and leave a channel through which bile could enter the pancreatic duct in 30 to 70 per cent of persons. The former figure was obtained by dissection and the latter by tests in which the papilla was occluded and fluid injected into the bile duct by several investigators.

Injection of bile and numerous other irritants into the dog's pancreatic duct at pressures sufficient to rupture tiny ductules produces severe pancreatitis. It is difficult to imagine how a differential pressure great enough to force bile into the pancreatic duct could occur under normal circumstances. In the dog, at least, pressure in the common bile duct is usually a little less than that in the pancreatic duct. The extremely high pressures that can occur with retching or vomiting are derived from an increase in general intra-abdominal pressure and are ap-

nausea, vomiting, constipation and abdominal distention are common. Although some episodes may last only a few hours, attacks often continue for as long as ten days. Opiates are required for relief. Occasionally the pathologic picture of destructive chronic pancreatitis is seen in patients who do not give a history of pain.

Significant physical findings consist of abdominal tenderness without the boardlike rigidity seen in acute hemorrhagic pancreatitis, often decreased bowel sounds associated with distention of the abdomen and occasionally enough jaundice to be detected grossly.

The most valuable laboratory finding is increased values for serum amylase and lipase during acute attacks of pain, although it must be remembered that this phenomenon may not be seen because so much destruction of pancreatic tissue may have occurred late in the course of the disease. If edema in the head of the pancreas is sufficient to produce jaundice, the concentration of serum bilirubin may increase to 4 or 5 mg per 100 ml.; the pigment is principally of the direct-reacting variety. The concentration of serum calcium may decrease, as described previously, and transient glycosuria may occur. Diagnosis in some patients is simplified when a roentgenogram of the abdomen discloses calcific deposits in the region of the pancreas (Fig. 3). When ileus is present, one may see dilatation of some loops of small intestine. If the gallbladder is still present, cholecystography may reveal evidence of cholelithiasis.

The progressive destruction of the pancreas and repeated attacks of severe pain lead to numerous sequelae, including diabetes mellitus, steatorrhea, malnutrition, pancreatic calcification, abscesses and pseudocysts, and addiction to opiates.

Specific medical treatment for the disease is unknown. The measures used during acute attacks are those for the treatment of acute pancreatitis. Between attacks, patients may be virtually symptomless unless sequelae of the disease have occurred. Tests should be made at intervals to determine the presence or absence of diabetes. Steatorrhea, when present, usually will be improved if a diet low in content of fats is combined with oral administration of pancreatin. Alcohol definitely provokes attacks in certain patients and should be avoided. Every care must be taken to prevent addiction to opiates, which occurs all too easily in this situation and renders treatment most difficult.

Surgical treatment often offers these sufferers much relief and there are many indications for its use.

Operations on the biliary tract. About half the patients who have relapsing pancreatitis have associated disease of the biliary tract. Surgical treatment of the associated condition often is followed by subsidence of the pancreatitis. A diseased gallbladder should be removed. The common bile duct should be explored to remove any stones that may be present. Drainage of the common duct by a T tube for six months to a year results in subsidence of the associated pancreatitis in many patients when the biliary tract has been diseased and in about half of the patients who do not have associated disease of the biliary tract. Obstructive jaundice persists occasionally and requires a sidetracking operation such as choledochoduodenostomy.

Operation to improve drainage of pancreatic juice into the duodenum. Many surgeons, stimulated by the good results reported by Doubilet and Mulholland, have employed sphincterotomy, a procedure in which the sphincter of Oddi is severed, usually through a transduodenal approach, after the papilla of Vater has been identified by passing an instrument through it via the common bile duct. Most surgeons agree that although good results often are obtained, failure is not uncommon. It is understandable that sectioning the sphincter of Oddi

Figure 3. Cholecystogram of patient with relapsing pancreatitis with calcification. The gallbladder functioned normally and contained no stones.

mouth during the acute phase, an injunction that ordinarily is enforced automatically by the anorexia which is present (3) Continuous suction on a tube placed into the stomach helps control vomiting, may minimize stimulation of pancreatic secretion by acid reaching the duodenum and prevents distention of the intestines as a result of the ileus that sometimes develops (4) Fluid and electrolytic balances are maintained by appropriate intravenous therapy (5) Use of anticholinergic drugs has been suggested on the grounds that they can diminish pancreatic secretion. (6) Calcium gluconate given parenterally may be needed, since there is often an appreciable loss of calcium into the regions of fatty necrosis. The amount needed depends on the concentration of calcium in serum, which should be checked periodically (7) It is well to keep in mind the fact that diabetes sometimes becomes manifest and may require treatment (8) Some evidence exists that antibiotics are beneficial in reducing the incidence of problems related to secondary infection

This plan of treatment, although logical, is somewhat empirical. Because acute edematous pancreatitis usually runs a self-limited course and gradually subsides over a period of four to seven days, it is not easy to assess accurately the relative importance of the measures that have been suggested. Definitive surgical treatment of disease of the biliary tract, when this is present, carried out when the pancreatitis is quiescent, is an integral part of treatment

Acute hemorrhagic pancreatitis. This form of acute pancreatitis may appear to result from progression of the edematous form of the disease or it may occur with dramatic suddenness without prior evidence of milder pancreatitis. The clinical picture is an intensification of that seen in edematous pancreatitis, with more rapid progression of symptoms and with the added feature of profound shock. The mortality rate is extremely high and many patients die within twenty-four hours of onset of the disease. If death occurs early, hemorrhage into the pancreas and a hemorrhagic exudate in the peritoneal cavity may be the principal pathologic findings. If the patient lives a few days longer, necrosis and gangrene of the pancreas, even to a point of complete destruction of the gland, are paramount. Those patients surviving a few weeks or more are prone to have abscesses or pseudocysts in the region of the pancreas which may com-

municate with adjacent viscera. The serum amylase is increased.

Treatment of shock demands immediate attention. Correction of the decreased blood volume by transfusion of liberal amounts of whole blood is most important. Although some surgeons favor immediate laparotomy with drainage of the region of the pancreas, the majority favor nonoperative management. Many persons are in such poor condition when first seen that laparotomy would appear to carry a prohibitive risk to the patient. Abscesses or pseudocysts in surviving patients should be drained at once. The principles of nonoperative treatment are the same as those described for acute edematous pancreatitis, with the added need for measures to counteract shock.

Relapsing Pancreatitis. In some unfortunate persons, attacks of pancreatitis are recurrent over a period of many years and produce a clinicopathologic picture described by the term "relapsing pancreatitis" or "recurrent pancreatitis." Animal experimentation indicates that extremely mild episodes of acute edematous pancreatitis can be followed by complete functional and morphologic recovery of the pancreas, whereas episodes of ordinary severity produce varying degrees of destruction of pancreatic tissue, with subsequent atrophy and fibrosis. Repeated attacks of inflammation, edema and even necrosis of pancreatic tissue progressively destroy functioning pancreatic parenchyma, leaving a fibrosed gland which sometimes shows zones of calcification, abscesses, pseudocysts or even enough destruction of the islets of Langerhans to cause diabetes. Males are affected about six times as often as are females.

The cause of relapsing pancreatitis, like that of acute pancreatitis, cannot be stated with certainty and the same factors are considered to be contributory. Alcoholic excess is frequently associated with relapsing pancreatitis and cholecystic disease has been noted in about 50 per cent of the subjects.

The outstanding symptom during exacerbations of relapsing pancreatitis is pain in the abdomen. It may be mild but is usually extremely severe. It may be felt in any part of the abdomen, but it is characteristically worse on the left and typically extends, through to the left upper lumbar region. It is variously described as colicky, cutting, piercing or boring and its severity may lead the patient to seek relief vainly by assuming unusual postures, doubling up in a chair or flexing himself around a pillow. Anorexia,

tum, displacing the stomach superiorly. The contents of pseudocysts are typically thick and dark or reddish brown.

Retention Cysts. True cysts of the pancreas are characterized by a lining of cuboidal or low columnar epithelium and by the presence of dilated pancreatic ducts within or adjacent to the wall (Fig. 5). Thirteen cases, approximately a fourth of Thigpen's series of pancreatic cysts, fell into this category. None of the patients presented a history of trauma, and gallstones or evidence of cholecystitis was present in less than a third at the time of operation. Evidence of pancreatitis was present in a third of the subjects, but it is difficult to say whether this was a cause or a result of the disease. Ten retention cysts were unilocular and three were multilocular. They varied from 4 to more than 20 cm. in diameter. Fluid in these cysts is usually yellow.

Cystadenomas. These are benign neoplasms in which the cysts are multilocular and, of course, lined with epithelium (Fig. 6). Seven occurred in Thigpen's series.

Cystadenocarcinomas. Four such lesions were found among the fifty-five patients with pancreatic cysts; one of these was associated with hepatic metastasis at the time of exploration. The cysts associated with this type of malignant tumor varied in size from that of a pear to 15 cm. in diameter. Microscopically, the growths were predominantly papillary cystadenocarcinomas, although mixed in one were regions of squamous cell epithelioma. Needless to say, this variety of

carcinoma of the pancreas is extremely rare and is not to be confused with the common adenocarcinoma of the pancreas.

Other Cystic Lesions of the Pancreas. Thigpen's series of fifty-five cystic lesions of the pancreas was completed by two cystic hemangioendotheliomas and one of each of the following: cystic adenocarcinoma of the islets of Langerhans, cavernous hemangioma, dermoid cyst, epidermoid cyst and a cyst of accessory pancreatic tissue.

Symptoms and Diagnosis of Cyst of Pancreas. A pancreatic cyst can become extremely large so gradually that the patient is unaware of it until he or his physician happens to palpate the tumor, which usually presents as a smooth, firm, rounded epigastric mass. Although symptoms may be denied in some instances, there is usually a feeling of tightness and pressure in the upper part of the abdomen or actual pain. An antecedent history of trauma, or of symptoms suggestive of pancreatitis or cholecystitis, is likely to be elicited in the case of pseudocysts, and symptoms of the last-named two conditions, when present, may overshadow the clinical picture. Anorexia and consequent loss of weight are common and chills and fever sometimes occur with pseudocysts. Jaundice is present in 5 to 10 per cent of patients who have pancreatic cysts. Steatorrhea appears to be present rarely.

The mass is firm and rounded. It feels cystic, lies in the upper part of the abdomen, is too tense to allow demonstration of a fluid wave, is typically not tender or only slightly

Fig. 4. Cyst with walls of fibrous connective tissue (pseudocysts) (Waugh, J. M.: *Surgical Diseases of the Pancreas*. In Walters, W.: *Lewis' Practice of Surgery*, vol. 7. W. F. Prior Co.).

cannot influence obstruction of pancreatic ducts distant from the sphincter.

Operations on the pancreas. In recent years increasingly more patients who have chronic relapsing pancreatitis have been treated by resection of a portion of the tail of the pancreas and implantation of the cut surface of the gland into a loop of jejunum made with the Roux en Y technique. The purpose of this operation is to permit retrograde drainage of pancreatic juice into the intestine. In many cases there will be several obstructions or strictures of the main pancreatic duct as it courses through the body and tail of the gland. To facilitate drainage of as much of the gland as possible, this part of the duct can be opened throughout a considerable length. The resulting pancreaticojejunostomy then becomes almost side to side (Puestow and Gillesby). Encouraging results have been reported to follow the use of this procedure in advanced cases of pancreatitis. Abscesses may require drainage. Pseudocysts may need external or internal drainage. If the disease is limited to the tail and body of the pancreas, where considerable degrees of calcification may occur, resection of this portion of the gland should be considered. Total pancreatectomy has been used for diffuse calcification and unbearable pain. The operation is formidable and is attended by late complications which rarely make it advisable.

Operations to decrease external pancreatic secretion. Partial gastrectomy, which results in diminution of the volume of pancreatic secretion, has been suggested as treatment for chronic relapsing pancreatitis. At present, data regarding its effectiveness are few and do not indicate that the procedure has much promise.

Operation to relieve pain. Splanchmicectomy has been performed to relieve pain and good results have been reported by some observers. Our results with it have been discouraging.

PANCREATIC CALCULI

Quite different from the calcification which sometimes occurs in the parenchyma of the pancreas in association with relapsing pancreatitis are calculi that sometimes develop in the pancreatic ducts. These stones are composed of calcium carbonate and calcium phosphate and in many respects they are similar to calculi of the salivary glands. They are grayish white, hard and irregularly shaped. They may vary in size

from 1 mm. to 7 cm. They may be single or may be multiple to the extent of several hundred.

Patients of all age groups are affected, but pancreatic calculi occur more commonly in patients who are between the ages of forty and sixty years. Males are affected three or four times as frequently as females. The etiologic factors are unknown.

Although the incidence at necropsy was thought to be 1 in 1500 to 1 in 3000, it is probably greater, according to Snell and Comfort.

The symptoms may be minimal or entirely absent but usually follow the pattern described under relapsing pancreatitis. Snell and Comfort list the following symptoms in order of frequency: abdominal colicky pain, steatorrhea, diabetes mellitus and, less frequently, jaundice. The diagnosis is confirmed by a roentgenogram of the abdomen. The treatment is surgical and consists of exposure and incision of the duct over the stone, with removal of the latter, careful exploration of the ducts often reveals multiple stones. After removal of the stones, a small T tube should be left in the duct for two or three weeks. There is rarely any drainage of pancreatic juice after removal of the tube. If parenchymal calcification is associated, it may be advisable to excise a portion of the gland.

CYSTIC LESIONS OF THE PANCREAS

Pseudocysts. These lesions of the pancreas are defined as cysts having walls composed of fibrous tissue without any epithelial lining (Fig 4). They accounted for twenty-four of the fifty-five cysts of the pancreas studied by Thigpen. Etiologic factors are believed to be pancreatitis, disease of the biliary tract and trauma. A history of trauma was obtained in four of the twenty-four subjects, and disease of the gallbladder, pancreatitis or a suggestive history of such was present in nineteen of the remaining twenty patients.

In other series, trauma has been reported to be a cause more frequently than would be indicated by these figures. Development of a pseudocyst after trauma to the abdomen may be an extremely slow process and months, or even a year or more, may pass before the cyst is recognized.

Pseudocysts may range in size from a few centimeters to as much as 35 cm. in diameter and are almost always unilocular. Such cysts may present themselves through the gastrohepatic omentum, displacing the stomach inferiorly, or through the gastrocolic omen-

stomach or a loop of small intestine. In recent years, the procedure of internal drainage of pancreatic cysts, first done in 1923, has been practiced increasingly and has given good results in the hands of many surgeons. It is especially useful in true cysts of the pancreas. Most pseudocysts respond well to prolonged drainage with or without marsupialization.

NEOPLASMS OF THE PANCREAS

Benign Tumors. Benign tumors of the ampulla of Vater are rare. They consist of polypoid masses of tissue which may not produce symptoms but which can cause biliary obstruction and jaundice. The surgeon dealing with presumed malignant neoplasms of the ampulla of Vater should keep in mind the possibility of the presence of these small benign polyps and avoid radical pancreatectomy for a benign lesion.

Sarcoma. Sarcoma of the pancreas occurs with extreme rarity; results of excision, when this has been possible, have been poor.

Carcinoma. Carcinoma of the pancreas is the commonest neoplasm of this organ; it constitutes 1 to 2 per cent of all carcinomas. Approximately 75 per cent of carcinomas of the pancreas originate in the head of the organ and only 25 per cent in the body or tail. Symptoms and surgical management differ with the location of the lesion, so that carcinoma of the head and that of the remainder of the pancreas can be profitably considered separately. Furthermore, the clinical features of carcinoma of the head of the pancreas and of carcinoma originating in the region of the ampulla of Vater have so much in common that these two lesions are best discussed together.

Carcinoma of the head of the pancreas and carcinoma of the ampulla of Vater.

Carcinoma of the head of the pancreas and carcinoma of the ampulla of Vater occur more frequently in males than in females and are commonest in the sixth decade of life.

Both these tumors are adenocarcinomas, but carcinomas originating from the ampulla or the papilla of Vater, as well as from the adjacent bile ducts, are more likely to have a papillary arrangement of cells and to be more differentiated histologically than are carcinomas of the pancreas itself. Metastasis to regional lymph nodes apparently occurs earlier in carcinoma of the head of the pancreas than it does in ampullary tumors and invasion of the perineural lymphatic vessels

is more common in growths originating in the pancreas. Ampullary carcinomas are often soft, whereas carcinoma of the head of the pancreas is typically hard. Carcinomas of the head of the pancreas usually are accompanied by intense fibrosis of the surrounding pancreas which may, if the ducts are blocked, involve the entire organ. Biopsy often shows only fibrosis even when carcinoma is present, an important point to remember during operations for this disease.

Obstructive jaundice becomes the most striking feature of both carcinoma of the head of the pancreas and carcinoma of the ampulla of Vater and actually may be the first detectable sign of disease in lesions of the ampulla. In carcinoma of the head of the pancreas, jaundice is usually preceded by a decline in health over a period as long as six months, during which time the patient may experience anorexia with associated loss of weight and progressive weakness and epigastric pain often referred to the back. The pain of pancreatic carcinoma is constant; it often is described as nagging or gnawing and appears to be intensified at night. Pain may be absent in ampullary carcinoma and when it occurs it is often episodic at first.

Jaundice usually occurs sooner or later in association with carcinoma in either region and, at the time surgical intervention is being debated, the problem often has resolved itself into the differential diagnosis of jaundice. The point of practical importance is to separate the patients who have intrahepatic jaundice, due usually to hepatitis, and who should not undergo operation, from those who have obstructive jaundice, due to choledochal stone or neoplastic obstruction, and who should have surgical treatment.

Points in favor of hepatitis include a history of exposure to the epidemic type of the disease or of prior blood transfusion, the absence of a palpable gallbladder, lack of significant pain, a predominance of indirect-reacting bilirubin in the serum early in the disease, positive results of cephalin-cholesterol flocculation tests and other similar tests which indicate parenchymatous disease of the liver, and the presence of some bile in the duodenum on duodenal drainage.

Patients who have obstruction of the common bile duct due to stone often give a prior history suggestive of cholecystitis or cholelithiasis. They usually have colicky intermittent pain associated with chills and fever that is different from the boring pain which

Figure 5. Retention cyst (true cyst) (Waugh, J. M. *Surgical Diseases of the Pancreas*. In Walters, W. Lewis' Practice of Surgery, vol 7 W. F. Prior Co.).

so and usually does not move with respiration. Unless the patient is experiencing an attack of acute pancreatitis, the values for serum amylase and lipase are usually within normal limits. Roentgenologic examination of the stomach using barium reveals displacement of the organ by the extrinsic mass. When the head of the pancreas is involved, widening of the curve of the duodenum often can be demonstrated by the same method. Calcium in the wall of a pancreatic

cyst occasionally may outline it well on plain roentgenograms of the abdomen. Other cystic enlargements which enter the differential diagnosis are cysts of the omentum, liver, ovary, kidney and spleen. Excretory urograms and sometimes even retrograde pyelography may be needed to exclude hydronephrosis.

Treatment of Pancreatic Cysts. The treatment of choice for any cyst of the pancreas is total excision, with preservation of as much of the normal pancreas as possible. If this proves to be impossible or to involve unwarranted risk to the patient, the alternatives are marsupialization or internal drain-

Figure 6. Multilocular cystadenoma of pancreas excised surgically (Waugh, J. M. *Surgical Diseases of the Pancreas*. In Walters, W. Lewis' Practice of Surgery, vol. 7, W. F. Prior Co.).

Thigpen had cystic lesions of the pancreas that could be excised readily. Excision is particularly important whenever possible in the case of neoplastic cysts, since if the lesion is malignant, as some are, it represents the only hope of cure.

Pseudocysts respond to external drainage by marsupialization more readily than do true cysts. By marsupialization is meant evacuation of the cyst, exploration of it to rule out the possibility of a malignant lesion and suture of the wall of the cyst to the skin, leaving an opening about 2.5 cm. in diameter. A large catheter is sutured in place to insure free drainage and in most subjects the resulting fistula soon closes. Continued drainage of pancreatic juice may continue for years in a few patients if further steps are not taken. A chronic fistula usually can be corrected satisfactorily by an operation in which the fistulous tract is dissected out so that its end can be implanted into the

pancreas, may provide a positive diagnosis. Falsely negative results are common, however, and the surgeon is often forced to rely on his own appraisal of the lesion based on gross inspection. Carcinomas of the ampulla may be small, soft and difficult to feel accurately and direct inspection of the papilla of Vater after the duodenum is opened may be necessary for certain diagnosis. If the neoplasm has spread, a diagnosis often can be made by biopsy of metastatic lesions in the liver, regional lymph nodes, omentum or elsewhere.

When the surgeon has satisfied himself that the patient has a carcinoma of the ampullary region or of the head of the pancreas, he must decide whether the disease is sufficiently localized to permit and warrant resection or whether he is forced to content himself with a palliative procedure designed to relieve jaundice and sometimes to forestall or correct obstruction of the duodenum. Since palliative procedures offer no hope of cure, resection is preferable. However, since resection in the presence of metastatic lesions which cannot all be removed is followed by no greater comfort and no longer survival than are palliative procedures and, because the operative mortality and morbidity rates in these patients are greater than they are in those subjected to simpler palliative procedures, resection is to be avoided in these circumstances. This is in contrast to many malignant tumors of the stomach and colon, for example, in which palliative resections are often indicated when technically feasible. Resection of the head of the pancreas involves removal of the duodenum, because the blood supply of these two organs is inseparable, and of the distal portions of the common bile duct and stomach, followed by anastomosis of the biliary tract, stomach and sometimes the tail of the pancreas to the intestine. Because the first successful resection of this type was performed by Whipple, in 1935, it is generally referred to as the Whipple operation. The presence of metastatic tumors in the liver, omentum, root of the mesentery of the small intestine and the lymph nodes around the aorta and celiac axis, as well as more distant metastasis, is a contraindication to performance of the operation.

In the absence of these findings, the surgeon must decide whether fixation of the lesion itself by local extension precludes its removal on technical grounds. Sometimes firm fixation posteriorly or malignant involvement surrounding the superior mesenteric

vessels makes it apparent that resection is impossible. On other occasions, the local resectability of the lesion can be determined only after preliminary dissection has been started, with incision of the peritoneum lateral to the duodenum and elevation of the duodenum and pancreatic head to find out whether the growth has involved the vena cava, portal vein or superior mesenteric vein. Extension of carcinoma around these veins is the commonest factor preventing resection when other factors appear favorable. A two-stage procedure applicable to this situation in which the portal vein is first ligated with the plan of removing it along with the growth ten days or two weeks later has been described by Childs. Ligation of the portal vein under these circumstances has been tolerated satisfactorily, but data are not yet available to prove that this extensive procedure produces results good enough to justify it.

Approximately 30 per cent of malignant lesions causing jaundice are found to be suitable for resection. Although resection in one stage is preferable, a few patients remain in whom resection appears warranted and technically feasible but whose general condition is so poor that the risk appears too great. In these, a two-stage procedure is applicable, the surgeon corrects the jaundice in the first stage and plans to perform the resection later if, and when, the patient's condition can be improved. Many different anatomic arrangements have been used to re-establish gastrointestinal continuity, to join the biliary tract to the intestine and to dispose of the remainder of the pancreas. The tail of the pancreas, if uninvaded by the malignant process, should be preserved to prevent the diabetes which would follow its removal. Some surgeons simply have tied its duct, oversewn its end and left it isolated from the intestinal tract, but in most instances digestion is improved if the cut end of the gland is implanted into the intestine. It is rational to arrange the parts so that bile and pancreatic juice enter the intestine before gastric contents do, so they can neutralize chyme at the anastomosis and so minimize the chance of formation of gastrojejunal ulcer, at the same time it is well to isolate the biliary and pancreatic systems from the main stream of food (Fig. 7).

The most satisfactory procedure in our hands has been end-to-end pancreaticojejunostomy with end-to-side choledochojejunostomy and end-to-side postcolic or antecolic antiperistaltic gastrojejunostomy. Suc-

may be described by some patients with carcinoma of the pancreas. However, it should be remembered that the presence, absence or quality of pain is not an unfailing guide in the differential diagnosis of obstructive jaundice, because some patients with jaundice from obstruction of the common bile duct by stone have no pain. The jaundice associated with stone in the common bile duct tends to fluctuate and is typically moderate in degree, because more often than not the obstruction is not complete. Early in the course of the disease, results of liver function tests indicate obstruction as opposed to intrahepatic jaundice, although later these results may not be clear cut. Because of cholelithiasis and cholecystitis, the gallbladder is usually thickened sufficiently so that it does not dilate to an extent whereby it becomes palpable.

In the presence of neoplastic obstruction of the bile ducts, the gallbladder is usually normal and can dilate hugely to become palpable. The generalization that in the presence of obstructive jaundice a palpable gallbladder indicates a malignant lesion and a nonpalpable gallbladder indicates stone is an old rule of thumb in medicine that constitutes Courvoisier's law. Although not infallible, this rule is extremely useful. The jaundice of neoplastic obstruction of the bile ducts is progressive, intense and unremitting. This type of jaundice is often thought of as painless and this is frequently so, especially when the lesion is of the ampulla. However, it should be clear that many patients with carcinoma of the pancreas have pain. Although they occasionally are palpable, these tumors cannot be felt in most patients in the early phase of the disease. Results of liver function tests carried out early in the course of the jaundice are suggestive of obstruction rather than of intrahepatic disease. Bile is not recoverable from the duodenum on duodenal drainage in the majority of patients who have carcinoma of the head of the pancreas and in about half of those with ampullary neoplasms. Gross blood is obtained in the duodenal contents in about 25 per cent of patients who have ampullary lesions. Deformities in the region of the ampulla can be seen in about a fourth of the patients with neoplasms in this region. Values for serum amylase and lipase are occasionally but not consistently increased.

With astute diagnosis, a few patients who have carcinoma of the head of the pancreas may be operated on before the onset of jaundice. Much more commonly, however,

the preoperative diagnosis is that of obstructive jaundice, the differentiation between obstruction due to stone and that due to neoplasm is sometimes almost certain and sometimes in considerable doubt. Adequate preoperative preparation is most important and may require a few days to as much as two weeks. Anemia should be corrected by transfusion of whole blood. A diet high in carbohydrate and protein and low in fat is given. It may be supplemented by intravenous administration of solutions of glucose and protein hydrolysate. Particularly important is administration of vitamin K to restore the often-depleted prothrombin to normal levels and prevent the bleeding that formerly contributed so much to the hazards of operations on jaundiced patients. If an increased prothrombin time does not return to normal after administration of vitamin K, considerable hepatic damage is present and the risk of operation is increased.

Once the abdomen has been opened through a right upper rectus or upper transverse incision, the surgeon's first task is to determine the nature of the lesion and, if it is malignant, whether or not it can and should be resected.

When biliary obstruction is caused by a stone impacted at the ampulla of Vater, cholecystitis and cholelithiasis usually are present, the gallbladder usually is not greatly dilated, the common bile duct is usually enlarged and may or may not contain palpable stones, there is no true tumor palpable in the region of the head of the pancreas, although the region of the ampulla may feel thickened, and there is, of course, no metastasis in the liver or elsewhere. The situation calls for exploration of the common bile duct, removal of the stone or stones, drainage of the duct with a T tube and cholecystectomy.

When obstructive jaundice is caused by neoplasm, the gallbladder is typically thin walled and distended, except for the unusual instances in which previous disease has rendered it inelastic or in which metastatic lesions blocking the hepatic or cystic ducts prevent bile from reaching it. Although a strategically placed carcinoma of the head of the pancreas may obstruct the common bile duct while the tumor is still small, the presence of large, firm, nodular, easily palpable tumors associated with extensive fibrosis of the gland is the rule. Immediate examination by the frozen-section technique of tissue for biopsy, taken with the Silverman needle or by removal of a wedge-shaped piece of

per cent, whereas for patients with carcinoma of the head of the pancreas it was 28 per cent. In carcinoma of the pancreatic head, three (12.5 per cent) of twenty-four potential survivors lived three years or more and three (16 per cent) of nineteen possible survivors lived five years or more. In carcinoma of the ampulla, nine (47 per cent) of nineteen potential survivors lived three years and five (38 per cent) of thirteen possible survivors lived five or more years after leaving the hospital. Patients who have this operation and die of recurrent carcinoma often live no longer than do others who have only palliative procedures. Patients who live three years have an excellent chance of living five or more years. Results of radical extirpation of carcinoma of the ampullary region leave no doubt that it is a worth-while undertaking (Fig. 8). Results of treatment of carcinoma of the head of the pancreas are discouraging, but since there is at present no other procedure that offers any hope of cure, radical resection is justifiable in properly selected cases.

Carcinoma of the body and tail of the pancreas. Approximately 25 per cent of carcinomas of the pancreas originate in the body and tail. It is not known why the incidence in the head is three times that in the body and tail. The sex and age of patients compare with those of patients having carcinoma of the head and the pathologic aspects are essentially the same. There is a great incidence of local invasion of the surrounding structures. The mesenteric vessels, celiac axis, aorta and vena cava frequently are surrounded and invaded before laparotomy is performed. Because initial symp-

toms are so often obscure, local invasion usually has occurred already at the time of exploration and accounts for the fact that resection is frequently not possible. Metastasis arises early and the first spread is usually to the liver, with the lungs next in order.

The symptoms differ somewhat from those seen in carcinoma of the head, although pain, which is the main symptom, is usually constant and unrelenting and more noticeable at night. Frequently it extends to the back and left side. Anorexia and loss of weight are frequent complaints and can be extreme even in patients who have had a tumor of the pancreas for only a short time. Jaundice is a late complication and usually indicates such an extensive tumor that resection is impossible. Nausea and vomiting are not infrequent and diarrhea and steatorrhea may be seen occasionally.

The laboratory data are typically not helpful in diagnosis. Some degree of anemia usually is present. The patient occasionally may have increased serum amylase. Roentgenographic findings are not particularly diagnostic, but distortion of the stomach, the colon or the upper portion of the small intestine may be noted.

Physical examination usually reveals nothing abnormal except a mass, which is often in the midportion of the epigastrium or a little to the left. It may be rather indiscrete, but at times it may be large. Venous thrombosis is seen frequently in patients with advanced carcinoma of the body and tail of the pancreas and usually heralds a hopeless situation. As a rule, diagnosis is not made and confirmed except at laparotomy.

Figure 8 Carcinomatous papilla of Vater removed by radical pancreatoduodenectomy (probe through papilla) with survival for nine and one-half years after operation (Vaugh, J. M.: Surgical Diseases of the Pancreas In Walters, W.: Lewis' Practice of Surgery, vol. 7. W. F. Prior Co.).

Figure 7 A satisfactory method of re-establishing pancreatic, biliary and gastrointestinal continuity after radical pancreateoduodenectomy (Vaugh, J. M. *Surgical Diseases of the Pancreas* In Walters, W. Lewis' *Practice of Surgery*, vol. 7. W. F. Prior Co.)

tion is applied constantly after operation to a Levin tube placed in the proximal limb of the jejunum for about three days, while fluid and electrolytic balance is maintained by appropriate intravenous therapy. Vitamins K, B and C are given daily and antibiotics should be administered to combat infection. The wound is freely drained by Penrose drains and often by Chaffin sump drains.

Should a biliary or pancreatic fistula develop, it is treated by suction applied through a catheter, with protection of the surrounding skin by ointments such as lanolin or aluminum paste. Such fistulae usually close spontaneously. The patient should be examined frequently for diabetes during the postoperative period, since transient hyperglycemia occasionally occurs requiring use of insulin. Although reimplantation of the pancreas into the jejunum greatly reduces the loss of fat in the feces, as compared with the loss in early techniques in which the pancreatic stump was simply closed, some patients require pancreatin to control steatorrhea. The dosage varies with the patient but may be as much as 30 tablets a day in extreme instances.

If the lesion is inoperable, the surgeon is justified in relieving the jaundice by making some type of anastomosis between the biliary and intestinal tracts. Gastroenterostomy should be performed as well when there is
e
o
and improves the patient's sense of well-

being. Various surgeons advocate such procedures as cholecystogastrostomy, cholecystoduodenostomy, cholecystojejunostomy or side-to-side choledochoduodenostomy for relief of jaundice. We know of no data to establish unequivocally one method as superior to the others and choledochoduodenostomy and choledochojejunostomy have given satisfactory results in our hands.

Bilateral block of the splanchnic nerves with alcohol often helps control the pain of pancreatic carcinoma.

Transduodenal excision of ampullary carcinoma frequently was used before the Whipple operation was developed. Results indicate that cure is so unusual after it that the procedure is best classed as palliative and is seldom, if ever, indicated at present.

The operative mortality rate for palliative operations performed because of carcinoma of the head of the pancreas and ampullary carcinoma has been extremely high in the past, figures of 50 per cent and even more being reported in the earlier literature. Since 1939 a pronounced decrease has occurred in the mortality rate, probably because of the preoperative and postoperative use of vitamin K and improvement in general supportive therapy. During the five-year period from 1949 to 1953 inclusive, the operative mortality rate in 212 operations performed at the Mayo Clinic for relief of jaundice due to obstruction of the bile ducts by malignant lesions of the pancreas or bile ducts was 75 per cent. Survivors almost always are relieved of jaundice. Survival after palliative operations is usually short, averaging about six months in carcinoma of the pancreas and approximately a year in ampullary carcinoma.

The operative mortality rate for the Whipple operation, which was 30 to 40 per cent at first, now appears to be approximately 20 per cent when all cases are considered. The higher rates obtained early in the development of the operation probably were associated with its employment in some patients who now would be considered inoperable. With better selection of cases, values considerably less than 20 per cent have been reported by some surgeons. Operative mortality and survival rates are better when the operation is performed for ampullary carcinoma than they are when the procedure is done for carcinoma of the pancreatic head. In a series of eighty-five cases from the Mayo Clinic, the operative mortality rate for patients undergoing this radical operation for carcinoma of the ampulla was 42

islet cell tumor can be considered: symptoms of insulin shock must appear when the patient fasts; the blood sugar at this time must decrease to 50 mg. or less per 100 ml.; symptoms must be promptly relieved after ingestion of glucose.

When these conditions are satisfied, a diagnosis of spontaneous hypoglycemia can be made. Causes of hypoglycemia other than islet cell tumors should be sought before operation is carried out. The following diseases occasionally may be associated with varying degrees of hypoglycemia: hepatic disease, including cholangitis, cirrhosis, hepatitis, carcinomatosis or von Gierke's disease; endocrine disturbances, such as hypofunction of the pituitary or adrenal glands, hypothyroidism or hyperthyroidism; lesions of the central nervous system, and some neuroses. It may be difficult to decide whether mild symptoms in neurotic patients are functional or perhaps due to islet cell tumors. A few patients have been encountered who secretly administered insulin to themselves to produce hypoglycemia. This bizarre form of malingering has been detected in some instances only by searching the patient's hospital room and finding hidden syringes and insulin.

Once the diagnosis of islet cell tumor is made, surgical exploration is indicated. Delay should be avoided since it can permit mental deterioration to occur as a result of repeated attacks of hypoglycemia, a phenomenon that can become irreversible. Immediately before operation, intravenous adminis-

tration of 1000 ml. of a 5 or 10 per cent solution of glucose should be started and continued throughout the operation to avoid hypoglycemia. An upper transverse incision gives adequate exposure of the pancreas after the gastrosplenic omentum has been divided. In some patients a tumor may be readily visible, but in many others a careful search is needed. The tail and body are first mobilized so that the gland can be inspected and palpated on both its posterior and anterior surfaces. If no tumor is found here, the head of the pancreas is examined on both surfaces, if necessary by reflection of the second part of the duodenum to the left and anteriorly after incision of the peritoneum lateral to it (Kocher's maneuver). A search should be made for accessory pancreatic tissue in such locations as the stomach, duodenum and gastrosplenic omentum, since heterotopic tissue sometimes can be the site of islet cell tumors.

If a tumor is found, it is excised. If a tumor is not found after a most careful search of the whole organ, the portion including the tail and body of the pancreas is removed, together with the spleen. Careful dissection of this specimen often reveals a tumor. If not, the resection may be continued, with removal of the remainder of the pancreas and the duodenum (Fig. 9), assuming a tumor to be in the pancreatic head. However, in most instances it is wiser to conclude the operation as a partial pancreatectomy in order to learn with certainty by the absence or continuance of symptoms whether sub-

Figure 9. A method of reconstruction after total pancreatectomy and duodenectomy (Waugh, J. M.: *Surgical Diseases of the Pancreas* In Walters, W. Lewis' Practice of Surgery, vol. 7. W. F. Prior Co.).

Although carcinoma of the body and tail of the pancreas should be most readily resected, rarely is it technically feasible because of the local extension. For example, resection was possible in only eight of 158 patients having adenocarcinoma of the body and tail of the pancreas operated on at the Mayo Clinic. The patient who survived the longest had recurrent adenocarcinoma two years later. In a group of ninety-eight patients followed after exploratory laparotomy and biopsy of the pancreas alone for this lesion, the average survival period after operation was three and a half months and the average survival from onset of symptoms to death was eleven months. We have been unable to find any mention in the literature of a patient alive and well without recurrence more than five years after resection of an unquestioned carcinoma of the body or tail of the pancreas.

Tumors of the Islets of Langerhans. The islets of Langerhans, more numerous in the tail and body than in the head of the gland, are made up of cells, some of which elaborate insulin. Neoplasms originating from this tissue may be histologically benign, may be malignant and metastasizing or may appear malignant cytologically but demonstrate no tendency to metastasize. Furthermore, tumors in each of these groups may or may not be "functioning tumors" associated with hyperinsulinism.

Howard and his associates, in 1950, presented a comprehensive review of hyperinsulinism and islet cell tumors of the pancreas and collected 398 tumors. Of the 224 tumors removed at operation, 211 were functioning and ten were nonfunctioning, in three instances, the status was unclear. Twenty-four of the tumors found at operation proved to be malignant. Their study showed that 174 of these tumors were found at necropsy, of which fifty-three were functioning and ninety-two were nonfunctioning; this point was undetermined in the remaining twenty-nine. At necropsy, thirteen proved to be malignant. It is understandable that the incidence of nonfunctioning tumors should be greater in lesions obtained at necropsy than in those obtained surgically since it is usually hypoglycemia which leads to the suspicion that such a tumor is present and prompts operation for it. About 5 per cent of functioning adenomas are multiple, although these are usually in the same part of the gland, they can be widely separated. As mentioned earlier, about 75 per cent of islet cell tumors originate in the body and

tail of the pancreas and 25 per cent are found in the head of the pancreas.

Nonfunctioning islet cell tumors and benign functioning adenomas are usually firm, grayish pink and fairly well delineated from normal pancreas, if not actually encapsulated. Adenomas which show cytologic evidence of malignancy usually are poorly encapsulated but otherwise are grossly similar to frankly benign growths. Malignant islet cell tumors are soft, brownish red, vascular, not encapsulated and may present metastasis. The usual size of the benign adenoma associated with hyperinsulinism is 1 cm. to 2 cm. Tumors smaller than 5 mm. in diameter rarely produce hyperinsulinism, and growths as large as 15 by 13 by 10 cm. have been reported. Whether benign or malignant, these tumors tend to present a histologic pattern somewhat resembling that of normal islets, frequently presenting arrangements of cells in the form of islands, acini, cords, strands or ribbons, according to Lopez-Kruger and Dockerty. Functioning benign adenomas usually are associated with a longer history of symptoms than are functioning malignant tumors.

With the exception of the few cases of nonfunctioning malignant islet cell tumors in which the clinical picture is that of a metastasizing adenocarcinoma, the symptoms of islet cell tumors are those of hypoglycemia resulting from an excess of endogenous insulin. The symptoms of hypoglycemia are many and varied. Mild fatigue and apprehension associated with pronounced hunger sometimes are predominant. Frequently symptoms referable to the central nervous system are especially prominent. Kepler and Moersch have stated that any one of the following states may dominate the clinical picture: apathy, irritability, restlessness, fatigue, anxiety, incorrigibility, negativism, automatic behavior, somnambulism, confusion, excitement, disorientation, drunken behavior, states of fugue, attacks of unconsciousness, delirium, mania, stupor and coma. It is not surprising that epilepsy, alcoholism or brain tumor frequently is suspected erroneously of being present. Because these patients often learn to ingest large amounts of carbohydrate for temporary relief of symptoms, they tend to become obese.

The diagnosis of hypoglycemia is made by determining the value for blood sugar at a time when symptoms suggestive of this disorder are present. Whipple has presented the following triad of findings which must be present before a diagnosis of functioning

Figure 10 Small islet cell tumor of the head of the pancreas necessitating total pancreatectomy. The patient in satisfactory condition ten years after operation (Waugh, J. M. *Surgical Diseases of the Pancreas* In Walters, W.: *Lewis' Practice of Surgery*, vol 7 W F Prior Co)

sequent radical total pancreatectomy (Fig 10) is necessary. Many patients in whom no tumor is demonstrated (46 per cent of fifty-six such patients in a series reported by Howard and associates) have satisfactory results after partial pancreatectomy. Symptoms are regularly relieved when adenomas are removed.

Islet Cell Tumors Associated with Peptic Ulcer. In 1955, Zollinger and Ellison described two patients with such intractable peptic ulcers that each underwent a series of operations culminating in total gastrectomy. In each case, tumors of the islets of Langerhans which did not cause hypoglycemia were finally found. The following year Ellison summarized the cases of twenty-four such patients collected from his own experience and from the literature. Of twenty-one patients whose sex was known, thirteen were women and eight were men. Their ages varied from nineteen to seventy-eight years. In nineteen cases the tumors were malignant and in five they were benign. In fourteen cases they were single and in ten they were multiple. In eleven of the patients with malignant disease, the tumors had metastasized from the pancreas at the time of recognition. Five patients had tumors of other endocrine glands as well. Hypoglycemia was present at some stage of the disease in only three patients.

In general, the ulcer diathesis accompanying these tumors was a fulminating one accompanied by excessive gastric hypersecretion not controlled by the usual medical or surgical measures. Ulcers often were located atypically in the esophagus, in the distal part of the duodenum or even in the jejunum. The tumors were discovered only at nec-

ropsy in nine patients who had undergone twenty-three operations for peptic ulcer and had finally died of some complication of an ulcer after an average of seventeen months. Tumors were removed at operation in eleven patients. Of these, three died soon thereafter of ulcer and were found still to have islet tumors. Three more died later of metastatic carcinoma; five were living at the time the report was made.

The assumption has been made that these islet cell tumors are in some way ulcerogenic. It has been postulated that they elaborate a humoral agent capable of stimulating gastric hypersecretion. An early suggestion that glucagon might be this agent remains unproved. In Ellison's words,

It seems reasonable, therefore, that the surgeon faced with the problem of patients with peptic ulceration or patients with pancreatic disease should look the possibility that an islet-cell tumor of the pancreas may be the causative factor. In these instances, a careful search for individual tumors or even resection of the body and tail of the pancreas might best be considered before subjecting the patient to total gastrectomy as a final, heroic means of controlling the acid factor.

Parenthetically, the intense fibrous tissue reaction which frequently surrounds gastrojejunal ulcers often lies in the region of the pancreas and can make accurate palpation of the pancreas for small tumors very difficult.

rived from the phrenic artery, the renal artery and the aorta. The lymphatics drain eventually into thoracic lymph nodes. Only the medulla receives a nerve supply derived primarily from the splanchnic plexus of medullated preganglionic fibers.

The cortex exhibits from the periphery inward three distinct areas: the zona glomerulosa, the zona fasciculata and the zona reticularis. There is evidence that these divisions of the cortex may be functional as well as structural. The glomerulosa may be considered as concerned with electrolyte exchange, the fasciculata with organic metabolism and the reticularis with androgen and estrogen effects. The medulla is structurally uniform and functionally elaborates two hormones, epinephrine and norepinephrine. The former comprises normally 75 to 80 per cent of the secretion and causes an increase of cardiac output, whereas the latter exerts a pressor effect by increasing peripheral resistance by vasoconstriction.

During the fourth week of embryonal life, mesothelial buds are found near the upper mesonephron which ultimately coalesce to form the adrenal cortex. Cortical buds not joining the main cellular mass may survive and exist as accessory adrenal cortical tissue in the region of the adrenal, kidney, spermatic cord, testis, broad ligament or ovary. The ectodermal medulla is derived from cells of the sympathetic ganglia which develop into chromophil cells from pheochromoblasts. These sympathochromaffin cells become surrounded by the adrenal cortical mass to form the medulla at about the seventh week of fetal life. Sympathetic ganglia along the aorta, at the aortic bifurcation and the carotid bifurcation are derived from sympathoblasts which may give rise to tumors similar to those of the adrenal medulla.

By the fourth month of intrauterine life, the adrenals exceed the kidneys in size and at birth they are one-third the size of the kidneys. During the first three weeks of postnatal life, the adrenal loses one-half of its size owing to degeneration of the fetal cortex and little change occurs thereafter until puberty. In adult life the usual ratio of adrenal to kidney is about 1:30. Although it has been recently demonstrated that accessory adrenal cortical bodies occur quite frequently in infants, and may persist in adults, they seldom are of clinical significance. These accessory bodies seldom produce tumors and usually cannot be detected by ACTH stimulation after total adrenalectomy. The anomalies of the adrenal of impor-

tance in surgery are unilateral agenesis, heterotopia (beneath renal capsule), accessory adrenal tissue, benign adrenal cysts and congenital bilateral adrenal cortical hyperplasia giving rise to abnormal sexual development.

The adrenal glands bilaterally share a common inaccessibility to surgical approach. Each gland is more independent of the kidney than has been commonly emphasized, though each lies in a superior extension of the perinephric fascia. Each lies superior and medial to the upper pole of the corresponding kidney with multiple fascial and vascular attachments to surrounding adipose tissue. The basal surface is often concave and a superior convexity extends upward along the aorta on the left and the vena cava on the right. The approach is more difficult in obese and heavily muscled subjects. Exposure is always easier in the female patient than in the male because of her less well-developed musculoskeletal structures.

The arterial blood supply is derived from the renal artery inferiorly, from the aorta mesially and one or more branches from the phrenic artery superiorly. Blood from the cortex passes into capillary networks which empty into the well-developed venous system of the medulla. The veins correspond in general to the arterial supply. The most difficult vessel to secure is the large but short vein leaving the midportion of the gland mesially and directly entering the vena cava on the right; on the left it is longer and easier to expose. The important vessels are secured by clamp and long ligatures, preferably of silk because of the depth of the wound and its low coefficient of friction.

Four different surgical approaches to the adrenals have been used and the route chosen is determined according to the problem and physical characteristics of the individual patient.

Cahill has advocated the transabdominal approach because it has the advantage of simultaneous bilateral exploration through a single incision. It has the disadvantage of requiring transperitoneal dissection and displacement of viscera and of being a more distant as well as less direct approach to the adrenal than is the transcostal approach. It is better adapted to thin patients (especially those with pheochromocytoma) and offers good opportunity for exploration for ectopic adrenal tissue as well as adnexal exploration in women.

Excellent exposure is accomplished by the transthoracic approach, but this carries the

THE ADRENAL GLANDS

By J. HARTWELL HARRISON, M.D., and
ROBERT E. DESAUTELS, M.D.

JOHN HARTWELL HARRISON was educated at The University. Virginians are not modest about the identification of The University. Harvard Medical School and the Peter Bent Brigham Hospital provided the broad surgical background upon which his urologic interests rest

ROBERT EUGENE DESAUTELS, a Vermont Yankee, was educated at Harvard College and Medical School. A musician by avocation, he is actively engaged in laboratory investigations in the field of urology

This subject in recent years has attained an increased importance which may be largely attributed to the work of Reichstein and of Kendall, respectively, each of whom separately isolated, identified and synthesized crystalline adrenal cortical steroids more than a decade ago. Since these advances, many intensive studies of adrenal cortical physiology have been made and directly resulted in the development of replacement therapy adequate to support life, even in the total absence of the adrenal glands. This adequate substitution therapy has greatly enlarged the scope of adrenal surgery and has altered the prognosis of patients having adrenal cortical insufficiency who require surgical intervention of any sort. The physician today can approach the problems of diagnosis and treatment of disorders of the adrenal glands with a confidence not possible ten years ago.

SURGICAL ANATOMY AND EMBRYOLOGY OF THE ADRENAL GLANDS

The adrenal glands are normally somewhat darker yellow in color and of firmer consistency than is the surrounding perinephric fat. They lie in a superior extension of the perinephric fascia. Their size varies considerably and is influenced by the physiologic state of the individual. Adrenal weight in previously healthy adults dying of accidental causes ranged from 58 to 11.3 gm (per pair) with an average value of 8.3 gm, whereas the weight of normal adrenals removed surgically from patients having hypertension or cancer averages 5 to 7 gm. each (10 to 14 gm. per pair), which shows an expected contrast to the post-mortem weight largely due to the great vascularity of these important endocrines. In shape, each has a somewhat conical center having ribbon-like superior and inferior extensions which vary in thickness according to the state of activity and circulation at the time of observation.

These glands are divided anatomically and physiologically into cortex and medulla. In contrast to the yellow cortex, the medulla is brown and develops a very dark brown upon staining with chromates, it is completely surrounded by the cortex. Selye has estimated that the flow of blood through the adrenals is at the rate of 6 to 7 cc. per gm. of tissue per minute. The blood is de-

ly, is de-

as a possible cause of the condition, since the secretion of ACTH is subject to neuro-hormonal stimuli from the hypothalamus.

The excessive production of glucocorticoids by the adrenal cortex results in a protein catabolic effect which leads to protein depletion and diminution of the muscular mass of the individual. The thin delicate skin and capillary fragility which is manifested by easy bruisability, as well as striae, are characteristic. Osteoporosis with loss of strength of bones and pathologic fractures is frequent. The accelerated protein breakdown results in increased gluconeogenesis and diminished carbohydrate tolerance. Insulin-resistant diabetes results from these processes. Accompanying the excessive protein breakdown is an excessive deposition of fat with abnormal distribution involving especially the face, back and trunk. The cervicodorsal fat pad has been characterized as a buffalo hump.

The anterior pituitary gland may show cytologic abnormalities characterized by a basophilic cytoplasmic hyalinization, vacu-

olization and degranulation. A basophilic tumor is present in one-third of the subjects. Less frequently, other types of pituitary tumor are encountered. The question is still unanswered in many cases as to whether the changes in the pituitary are primary, or secondary to those in the adrenal cortex. In about 30 per cent of the patients, an adrenocortical tumor is present and at least one-half of these neoplasms prove to be malignant. Unilateral hyperfunctioning tumors are often associated with diminished size and function of the contralateral gland. A small percentage of patients exhibit no structural abnormality of the adrenal glands grossly or histologically. However, at operation the glands always appear enlarged and physiologically hyperactive with an excessive degree of vascularity. When the lesion is due to adrenocortical hyperplasia, the glands at operation are found to be enlarged and to have a dark brown color, instead of the normal canary yellow color of the adrenal. Small adenomas may be found in the cortex associated with these changes. Histologically,

Figure 1 A, Pure Cushing's syndrome in a man, thirty years of age, exhibiting obesity, striae, bruisability, moon face, osteoporosis, weakness, impotence and loss of muscle due to hyperplasia of the adrenal cortex and corrected by bilateral adrenalectomy

B, Example of intergrade between Cushing's syndrome and virilism in a woman, aged thirty years, having hirsutism, amenorrhea, hypertension, great muscularity, hypertrophy of clitoris, diabetes and high excretion of androsterone (courtesy of Dr Harry Friedgood) due to carcinoma of the adrenal cortex.

C, The ultimate extreme of virilism in a female, aged twenty-two years, shown by bodily configuration, muscular development and hirsutism. Amenorrhea, hypertrophy of the clitoris and a markedly elevated 17-ketosteroid excretion characterized this patient's state of virilism caused by adrenal cortical hyperplasia involving primarily the zona reticularis (Harrison, J. H., and Laidlaw, J. C. S. Forum, vol. 4).

limitation of a unilateral operation at that session. It is indicated only in the case of very large tumors.

The bilateral posterior transcostal route with the patient flexed at the trunk in the prone position permits exploration of each gland simultaneously with minimal disturbance of other viscera. Subperiosteal resection of the eleventh and twelfth ribs is necessary on the right for adequate exposure and also is often desirable on the left. The approach is extrapleural and subdiaphragmatic, the kidney on each side being displaced inferiorly. This approach is of particular value when an adrenal tumor is suspected but has not been localized preoperatively, and when bilateral adrenalectomy is being carried out, especially in a thin patient. The posterior approach, though most direct, has the limitation of a small operative field with restricted visualization demanding two to three retractors in the wound.

The posterolateral approach affords a wide field of operation, with direct access to the suprarenal region on one side at a time, and is extremely useful when an adrenal tumor has been accurately localized prior to operation or when the patient is too large or obese for an approach via the posterior route.

The anatomic relations are the guiding features in surgery of the adrenal when it is being performed for hyperplasia, neoplasm, cyst or for removal of the normal gland. Variations in blood supply must be expected, especially when a tumor is present, and increased vascularity as well when hyperplasia is present.

CLINICAL PATTERNS OF HYPERADRENOCORTICISM

The pathologic states apparently mediated by hyperfunction of the adrenal cortex present a wide variety of conditions which have been classified clinically into Cushing's syndrome at one extreme and the adrenogenital syndrome at the other extreme. Between these two extremes are seen varying examples of the mixed syndrome, exhibiting features of both, in which one or the other predominates according to whether the glucocorticoids (zona fasciculata) or the sex hormones (zona reticularis) are being produced in excess, but in which both are participating to an abnormal degree (Fig. 1).

Cushing's Syndrome. Cushing's syndrome, properly defined, refers to the clinical picture described in 1932 by Harvey Cushing and known as pituitary basophilism. The exact cause of this condition is unknown

However, the clinical manifestations are those of hyperadrenocorticism. An antecedent history of prolonged periods of stress, worry and physical hardship has been noted in some of these subjects. It has been the impression of some physicians that this disease is on the increase. The disorder has been comparatively rare, it occurs most frequently in young adults and is three to five times more common in females than in males. Cushing attributed the disease to the basophil adenoma of the anterior pituitary gland. He also noted the frequent association of basophil tumors of the pituitary and either hyperplasia or tumor of the adrenal cortex.

It has been established that adrenocorticotrophic hormone secreted by the anterior pituitary gland controls the function and structure of the normal adrenal cortex. It is believed by some that ACTH is secreted by basophilic cells which indicates that perhaps abnormalities of the basophil function are involved in initiating disorders of the adrenal cortex. It is significant that certain patients with Cushing's syndrome have a remission following pituitary irradiation and the remission has been sustained in approximately one-sixth of these.

In one instance, three years after total adrenalectomy for hyperplasia causing Cushing's syndrome, a huge chromophobe adenoma of the pituitary became apparent and was surgically removed. High blood levels of ACTH became normal after hypophysectomy, and deep tanning of the skin disappeared. This case concretely illustrates pituitary-adrenal relations in Cushing's syndrome.

Kepler and others have suggested that adrenocortical hyperfunction is the initial event. This is supported by the numerous instances in which adrenocortical hyperplasia or tumor occurs without a demonstrable basophilic adenoma. The recent clinical and pathologic studies of Heinbecker furnish further evidence that the primary disorder arises in the adrenal cortex and may cause the changes in the pituitary gland described by Cushing. There is no doubt that the clinical picture is mediated by the adrenal cortex, since removal of this hyperfunctioning tissue has usually resulted in a reversal of the clinical picture. The intensive administration of 11-17 oxygenated cortical steroids does reproduce the symptoms and signs exhibited by patients with Cushing's syndrome as well as induce pituitary changes. The hypothalamus has been under suspicion

as a possible cause of the condition, since the secretion of ACTH is subject to neuro-hormonal stimuli from the hypothalamus.

The excessive production of glucocorticoids by the adrenal cortex results in a protein catabolic effect which leads to protein depletion and diminution of the muscular mass of the individual. The thin delicate skin and capillary fragility which is manifested by easy bruisability, as well as striae, are characteristic. Osteoporosis with loss of strength of bones and pathologic fractures is frequent. The accelerated protein breakdown results in increased gluconeogenesis and diminished carbohydrate tolerance. Insulin-resistant diabetes results from these processes. Accompanying the excessive protein breakdown is an excessive deposition of fat with abnormal distribution involving especially the face, back and trunk. The cervicodorsal fat pad has been characterized as a *buffalo hump*.

The anterior pituitary gland may show cytologic abnormalities characterized by a basophilic cytoplasmic hyalinization, vacu-

olization and degranulation. A basophilic tumor is present in one-third of the subjects. Less frequently, other types of pituitary tumor are encountered. The question is still unanswered in many cases as to whether the changes in the pituitary are primary, or secondary to those in the adrenal cortex. In about 30 per cent of the patients, an adrenocortical tumor is present and at least one-half of these neoplasms prove to be malignant. Unilateral hyperfunctioning tumors are often associated with diminished size and function of the contralateral gland. A small percentage of patients exhibit no structural abnormality of the adrenal glands grossly or histologically. However, at operation the glands always appear enlarged and physiologically hyperactive with an excessive degree of vascularity. When the lesion is due to adrenocortical hyperplasia, the glands at operation are found to be enlarged and to have a dark brown color, instead of the normal canary yellow color of the adrenal. Small adenomas may be found in the cortex associated with these changes. Histologically,

Figure 1. A, Pure Cushing's syndrome in a man, thirty years of age, exhibiting obesity, striae, bruising, impotence and loss of muscle due to hyperplasia of the adrenal enucleotomy.

B, Cushing's syndrome and virilism in a woman, aged thirty years, having great muscularity, hypertrophy of clitoris, diabetes and high excretion of androsterone (courtesy of Dr. Harry Friedgood) due to carcinoma of the adrenal cortex.

C, The ultimate extreme of virilism in a female, aged twenty-two years, shown by bodily configuration, muscular development and hirsutism. Amenorrhea, hypertrophy of the clitoris and a markedly elevated 17-ketosteroid excretion characterized this patient's state of virilism caused by adrenal cortical hyperplasia involving primarily the zona reticularis (Harrison, J. H., and Laidlaw, J. C.: *S. Forum*, vol. 4).

Figure 2. A, A man, aged twenty-two years, having a moon face, obesity, striae, hypertension and weakness due to adrenocortical hyperplasia which was treated by bilateral total adrenalectomy. B, This shows the striking change and improvement in the patient five months after adrenalectomy (Courtesy of Dr G W. Thorn.)

usually one finds hyperplasia of the zona fasciculata when the clinical condition is pure Cushing's syndrome. Unilateral adrenocortical hyperplasia is rarely seen

Other associated changes which have been reported are carcinoma of the pancreas, cysts of the pancreas, pancreatitis, infarcts of the pancreas, fatty infiltration of the liver, nephrosclerosis and renal calcinosis, and 80 per cent of the patients have a marked degree of osteoporosis. Generalized arteriosclerosis and cardiac hypertrophy are also found. Atrophy of the ovaries in the female patients and diminution in size and softening of the testes in men are common.

Obesity is a common feature of the disease in both sexes. It is truncal in distribution and the cervical dorsal fat pad, or buffalo hump, is characteristic. Thinning of the skin with multiple bruises as a result of increased capillary fragility is common. Abdominal and thoracic striae are common to both sexes. An intensely reddened countenance is frequently observed and hypertension, muscular weakness and easy fatigability are out-

standing symptoms (Fig. 2). Erythremia, glycosuria and osteoporosis are frequent concomitants. Polyphagia, polydipsia and polyuria are accompaniments of insulin-

Amenorrhea in females and impotence in males are common. Hirsutism occurs in the majority of women affected, but true virilization does not occur with the primary hyperglucocorticoid state (Fig. 3). Profound personality changes occur with increased irritability in some, progressing at times to a major psychosis, usually of the depressive type. Acne is commonly found and patchy cutaneous pigmentation may occur. The skin is surprisingly delicate and easily injured. There is a greatly increased susceptibility to

to heal per primum when asepsis is strict.

The laboratory findings in Cushing's syndrome may be listed as follows: decreased

glucose tolerance, hyperglycemia and glycosuria; a hematologic picture characterized by eosinopenia, lymphopenia, leukocytosis and erythremia; increased urinary corticosteroid excretion (17-hydroxycorticoids); normal or elevated 17-ketosteroid excretion; decreased serum chloride and potassium concentration; increased serum carbon dioxide content; osteoporosis demonstrated by roentgenograms of the skeleton; albuminuria. When the underlying pathologic lesion is carcinoma of the adrenal cortex, the 17-ketosteroids are usually elevated, especially the beta fraction.

Adrenogenital Syndrome (Virilism). This form of hyperadrenocorticism is found at the other extreme of the spectrum from the hyperglucocorticoid state of Cushing's syndrome. The condition is attributed to excessive production of androgens by the adrenal cortex. Between these two extremes are found various intergrades with varying clinical manifestations, according to the degree of involvement of the zona fasciculata and zona reticularis by the enhanced physiologic processes. As a consequence of the virilizing properties of the hormones elaborated, there may result female pseudohermaphroditism at birth, precocious puberty in the preadolescent male and heterosexual development in the preadolescent and adult female. In

addition to their androgenicity, these hormones have a markedly anabolic effect on protein metabolism. Thus, patients with pure Cushing's syndrome present evidence of protein depletion and loss of muscle mass, whereas those with a pure adrenogenital syndrome show signs of protein conservation and increased muscle mass.

According to Wilkins, postnatal adrenal virilism in females prior to puberty is almost without exception due to adrenal cortical tumor. Virilization may begin during the first few months of life and progresses rapidly. Pubic and axillary hair develops and there is hypertrophy of the clitoris. In the male, there is a picture of macrogenitosomia praecox. Rapid growth of muscle and skeleton is characteristic. Varying degrees of obesity may be seen along with the increased muscularity according to the amount of activity of the zona fasciculata. Very high levels of 17-ketosteroid excretion are seen. The differential diagnostic problem is with regard to whether or not there is congenital adrenal cortical hyperplasia or tumor. With the former, there is a typical response to the administration of cortisone resulting in inhibition of the adrenocortical activity and an improvement in the clinical condition.

The adrenogenital syndrome usually be-

Figure 3 A, A woman, aged twenty-three years, six months after the development of moon face and other early signs of Cushing's syndrome due to an adrenocortical adenoma on the left side. B, Photograph of patient six months after surgical removal of adenoma of the adrenal cortex.

Figure 1 A, Virilism in a twenty-eight-year-old female characterized by muscular development and hirsutism from the age of eleven years and amenorrhea from the age of eighteen, due to tumor of the adrenal cortex classified as carcinoma histologically and reacting as such physiologically by failure to respond to ACTH. B, Striking decrease in hirsutism and appearance of more feminine contours three months after removal of adrenal cortical carcinoma from this patient. Menses became regular and the patient continued to be well ten years later. A solitary left pulmonary metastasis was removed seven years after primary adrenal carcinoma was removed. This metastasis caused no endocrine or clinical disturbance though it showed the same histologic features as the original tumor.

gins at ages varying from adolescence to before the menopause. The majority of cases are probably due to tumor, but adrenocortical hyperplasia, especially involving the zona reticularis, may be the cause (Fig. 1 C). The development of secondary masculine characteristics due to increased androgens and the suppression of feminine characteristics occur simultaneously. Hirsutism involves the face, extremities and trunk. The hair of the scalp may be thin and occasionally one sees not only temporal recession but actual baldness. Irregularity of the menses which become scanty and ultimate cessation of the menses occur in the majority of patients. Libido is diminished, hypertrophy of the clitoris and simultaneous diminution in the size of the breasts, ovaries and uterus occur. The breasts become more masculine in contour. Deepening of the voice, extreme degrees of muscular develop-

ment and male configuration are striking. The condition differs from Cushing's syndrome not only in the metabolic alterations observed, but also in the natural course of the disease which in the case of virilism may occur over a period of many years (Fig. 4). The changes in Cushing's syndrome usually come about within a period of about two to three years.

In the adrenogenital syndrome, the pituitary gland does not usually show the changes found in Cushing's syndrome. Also, the pathologic changes in the liver, kidney, pancreas, muscle, bone and reticuloendothelial system are absent in pure virilism, but these changes may be present in the various intergrades between the two extremes of the spectrum. Patients having the mixed syndrome exhibit the characteristics of virilism shown by masculinization which usually predominates in the picture, as well as the metabolic ab-

normalities of Cushing's syndrome. These mixed pictures may be produced by adrenocortical hyperplasia perhaps more often than by tumor, though the latter may also be productive of this bizarre complex picture. Patients having the mixed syndrome will exhibit hirsutism, amenorrhea, hypertrophy of the clitoris, hypertension, obesity, masculine extremities with increased muscular development, plethora, seborrheic dermatitis, glycosuria, hyperglycemia, cutaneous striae, erythremia and extremes of personality change. Patients with virilism show very high levels of urinary 17-ketosteroids, ranging from 25 to 90 mg. per twenty-four hours. When carcinoma is present, there is a high level of the beta fraction of 17-ketosteroids. There may be no elevation of 17-hydroxycorticoids but in those having the mixed syndrome this will be present. High levels of androgens measured biologically can be recovered in the urine of patients with virilism.

The various causes of virilization in women must be considered in the differential diagnosis. The ovarian lesions which may produce virilism are arrhenoblastoma, Leydig cell tumor, diffuse luteinization or hyperthecosis, and polycystic disease of the ovaries (Stein-Leventhal syndrome). Palpation of a pelvic mass directs attention to the ovary, but, unfortunately, the tumors are frequently too small to be so detected. Leiomyomas of the uterus which are incidental must also be differentiated. A small number of patients with so-called adrenal rest tumors of the ovary have been described. Young emphasized the necessity of considering ovarian tumors in the differential diagnosis of virilism and recommended that preliminary pelvic exploration be carried out prior to adrenal surgery when no localizing evidence of an adrenal lesion could be demonstrated. When the lesion is primary in the ovary, an excessive response to ACTH is not to be expected in the steroids excreted in the urine. At pelvic exploration, careful examination of the adrenal area should be carried out. However, not finding pathologic change under these circumstances is not necessarily significant because intra-abdominal palpation of the adrenals may be unsatisfactory. Fairly large tumors may not be apparent when intra-abdominal palpation via a pelvic laparotomy exposure is carried out. Definitive suprarenal exploration is necessary for accuracy.

Primary Aldosteronism. A new clinical syndrome has been recently described by Conn, designated primary aldosteronism,

which causes a biochemical state of hypokaliemic alkalosis. Relatively few cases have been reported in the literature, but an increasing number of instances of hyperaldosteronism, both primary and secondary, are gradually being discovered.

Conn has described the clinical picture as being characterized by intermittent tetany, paresthesia, periodic severe muscular weakness and paralyses, polyuria, polydipsia, hypertension and no edema. In its fully developed state, the condition exhibits excessive amounts of a sodium-retaining corticoid in the urine, severe hypokaliemia, hypernatremia, alkalosis and a renal tubular defect in the reabsorption of water. There is no increase of excretion of 17-ketosteroids or of 17-hydroxycorticoids. The relative lack of important symptomatology at extremely low levels of serum potassium has been emphasized.

Operation upon the first patient described as having this condition was performed by Baum who found a well-encapsulated adenoma of the adrenal cortex 4 cm. in diameter. The cells of this tumor were laden with lipid material and bioassays of the tumor tissue gave values for aldosterone seventy-five to one hundred times greater per gram than that found in beef adrenal. The opposite adrenal gland showed thinning of the cortex and the atrophy was confined to the zona fasciculata. There was no atrophy of the zona glomerulosa. Chemical analysis of muscle biopsy specimens showed a great excess of intracellular sodium and marked decrease in the amount of intracellular potassium. Renal biopsies showed severe arteriosclerosis in all sections and a diffuse vacuolar change in the tubular epithelium thought to be hydropic degeneration. Areas of necrosis and also renal calcinosis were observed. This patient was only thirty-four years of age and the severe arteriolar lesions were attributed to excessive activity of the sodium-retaining steroid aldosterone.

Within one day following removal of this adenoma, the urinary excretion of sodium increased greatly and a marked retention of potassium occurred. Hypernatremia and hypokaliemia disappeared by the sixth postoperative day and serum values for sodium and potassium were normal thereafter. Proteinuria, polyuria and polydipsia disappeared in six days. Blood pressure fell from 170/100 to a level of 120/70 in eighteen days. Bioassays for urinary sodium-retaining corticoids after operation gave normal values. The patient became completely symptom free. It is of especial interest that though

this lesion seemed to cause atrophy of the contralateral adrenal in the zona fasciculata, it did not cause any rise in 17-hydroxycorticoids and 17-ketosteroids which were also normal both before and after operation.

This syndrome of primary aldosteronism has been clearly established by Conn. Within six weeks of his initial report, four additional cases typical of this condition were recognized by others and in each of the patients an adrenal cortical adenoma was found. In another patient, the finding of an adenoma was made at autopsy. Wyngaarden reported one patient in whom no adenoma was found at autopsy, though clinically the individual had all the characteristics of this syndrome. This suggests that the syndrome can occur without an adenoma.

suggests that, since the bioassay for urinary aldosterone is impractical for broad clinical use, serum bicarbonate and potassium levels be determined routinely as a screening procedure on all hypertensive patients. Hypokalemic alkalosis, unexplained by other conditions, should be regarded as an indication for careful adrenocortical study and exploration.

DIFFERENTIAL DIAGNOSIS AS TO CAUSE OF HYPERADRENOCORTICISM

In the differential diagnosis of these states, one is presented with a varying history and

findings, depending upon whether one is dealing with Cushing's syndrome, virilism or the mixed syndrome with its bizarre manifestations. The consideration of major importance is whether the disease is being

Figure 5. Plain film of the abdomen showing the shadow of a round tumor above the kidney in a man, aged forty years, having essential hypertension. At exploration this proved to be a large cyst of the adrenal gland with accompanying cortical atrophy on that side. Normal adrenocortical activity was found in both preoperative and postoperative studies

Figure 6. Tomogram in conjunction with excretory urogram in obese woman with virilism. The renal and adrenal areas are clearly demarcated showing no evidence of tumor and illustrating excellent detail without oxygen instillation.

Figure 7. Urinary steroid response to the eight-hour intravenous infusion of ACTH in the normal patient, in a patient with Cushing's syndrome due to adrenal cortical hyperplasia and in a patient with virilism due to adrenal carcinoma. The lack of response in the patient with carcinoma indicates the autonomous nature of the tumor. The hyperactive response in the patient with hyperplasia in contrast to the response in the normal patient and in the patient having carcinoma is significant in the differential diagnosis (Harrison, J H, and Laidlaw, J C S Forum, vol 4).

mediated by bilateral hyperplasia of the adrenal cortex, carcinoma of the adrenal cortex, adenoma of the adrenal cortex or a primary tumor of the ovary. A plain film of the abdomen (Fig. 5) and both excretory urography (Fig. 6) and retrograde pyelography may yield valuable information. Aortography is seldom necessary. Carbon dioxide injection into the retroperitoneal presacral area has replaced the use of oxygen because of its greater solubility and therefore lesser hazard of gas embolism. The limitations of the method must be recognized and it must be remembered that frequently masses of fat in the perinephric area have been mistaken for adrenal tumors. As high an error as 50 per cent has been reported with this latter technique alone. All of the diagnostic methods at one's disposal must be brought to bear in order to reach an accurate preoperative diagnosis.

The normal 17-ketosteroid excretion in the female ranges from 4 to 10 mg. per twenty-four hours. The normal 17-hydroxycorticoid excretion ranges from 4 to 6 mg. per twenty-four hours. With 25 clinical units of ACTH administered intravenously over a period of eight hours, the 17-ketosteroid excretion normally can be expected to rise to about 16 to 18 mg. and the 17-hydroxycorticoids can be expected to rise from the normal level up to 25 mg. (Fig. 7). When bilateral

adrenal cortical hyperplasia is present, resting levels of steroid excretion are high and an excessive rise in steroid excretion is expected as a result of ACTH stimulation. A level of 17-ketosteroid excretion may be from 30 to 60 mg. in twenty-four hours, and the elevated excretion of 17-hydroxycorticoids, when hyperplasia is present, may be a resting level of 20 to 30. Following administration of 25 clinical units of ACTH, the 17-hydroxycorticoid level may rise to 70 or even over 100 mg. Likewise, when adrenal cortical hyperplasia is mediating the disease process under consideration, Wilkins has shown that by administering 100 mg. of cortisone acetate per day a decrease of the excessive levels of corticoids in the urine can be produced (Fig. 8), presumably as a result of an inhibitory controlling effect by the pituitary on the hyperplastic glands. When adrenal cortical carcinoma is producing the clinical picture, one usually does not get a response as a result of stimulation with ACTH, and inhibition with cortisone administration does not occur. There have been a few exceptions to this, but, in general, these tests have served as a valuable differential diagnostic measure. When the clinical picture is due to adenoma of the adrenal cortex, a variable response may be obtained as a result of ACTH stimulation or cortisone inhibition. Failure to respond on the part of

ADRENAL INHIBITION WITH CORTISONE

TUMOR VS HYPERPLASIA

an adenoma has been observed as has a definite response to stimulation and inhibition in other cases. Such findings would most likely depend on the degree of biologic autonomy of the individual tumor and perhaps to some extent on its degree of differentiation, both physiologic and histologic. When physiologic evidence of an adrenal cortical tumor is found by these tests, increased efforts should be made in order to locate accurately its position. Adequate preparation of the patient and an excellent plain film are of great value. In addition, serial tomography has been helpful without, and in conjunction with, carbon dioxide instillation via the presacral route. The final certain method of localization is

logic physiology produced by lesions of the adrenal cortex. Hyperplasia of the adrenal cortex may involve predominantly any one of the three zones. In Cushing's syndrome, hyperplasia of the zona fasciculata is usually predominant. Hyperplasia of the zona glomerulosa is sometimes seen in individuals with hypertensive vascular disease, especially in those who have been on a salt-restricted diet. Hyperplasia of the zona reticularis may

be borne in mind when tumors of the adrenal cortex are being considered. The following simple classification of tumors of the adrenal cortex is suggested:

1. Tumors without apparent function
 - a. Cysts of the adrenal cortex
 - b. Adenoma of the adrenal cortex
 - c. Carcinoma of the adrenal cortex
2. Tumors with hormonal function
 - a. Adenoma
 - b. Carcinoma

Benign asymptomatic adenoma of the adrenal cortex occurs quite frequently and may be considered to be not pathologic. However, unknown factors may stimulate

stimulation of the adrenals and showing signs of virilism, there should be the relatively simple procedure of laparotomy and pelvic exploration in order absolutely to rule out a possible responsible ovarian lesion. Adrenal exploration is carried out subsequently when a tumor is not found in the ovary. At the time of pelvic laparotomy, palpatory exploration of the adrenals may reveal the presence of a tumor.

PATHOLOGY OF ADRENOCORTICAL TUMORS

Continued efforts are being made to correlate the histologic findings and the patho-

35 per cent of persons ex post-mortem

have small adrenal cortical adenomas. It is to be remembered also that adrenal cortical adenomas may occur in ectopic adrenal tissue and also in heterotopic adrenal tissue beneath the capsule of the kidney. Cysts of the adrenal cortex are considered as congenital lesions and may attain considerable size which may result in pressure atrophy of that adrenal gland. Only a few of these have been reported which had attained sufficient size to cause symptoms. Displacement of the kidney may be noted on palpation and on roentgenographic investigation as an incidental finding. Clinically they cannot be differentiated from a solid tumor except by surgical exploration or needle aspiration.

The nonendocrine carcinoma of the adrenal cortex may be confused clinically with renal cell carcinoma (Fig. 9) and may invade the kidney (Fig. 10), causing hematuria as the initial symptom. The tumor may be discovered as a result of its mass, and displacement of the kidney may be seen in the roentgenograms, either plain or pyelographic. The cell may have a clear to granular cytoplasm and, in contrast to the adenoma, it grows through its capsule and exhibits many mitotic figures with invasion of veins. Occasionally such neoplasms may develop bilaterally and they may also be found in aberrant adrenal cortical tissue. Metastases occur by hematogenous routes to the lungs and liver. Retroperitoneal nodes may be involved by lymphatic extension and direct growth. These tumors are usually found in adults from the third to the seventh decade of life.

The functional tumors of the adrenal cortex, whether adenomas or carcinomas, may produce the adrenogenital syndrome, Cushing's syndrome, the mixed syndrome, femini-

Figure 9. A right retrograde pyelogram showing deformity of the upper portion of the renal pelvis and absence of filling of the upper calices in a twenty-eight-year-old physician brought to the hospital in shock as a result of a severe renal hemorrhage. The hemorrhage and pyelographic findings were due to adrenal cortical carcinoma invading the kidney.

zation syndrome, primary aldosteronism and miscellaneous changes such as gynecomastia, urinary excretion of chorionic gonadotropin or the recurrent hypoglycemic episodes described by Thannhauser. Histologic characteristics do not differentiate the functional from the nonfunctional tumors of the adrenal cortex. It is possible that histochemical studies ultimately may discern detectable differences. The age distribution is quite different from that in nonfunctioning tumors

Figure 10. Photomicrograph of the kidney and invading adrenal cortical carcinoma from the patient whose right pyelogram is shown in Figure 9. The adrenal cortex lies beneath the intrinsic capsule of the kidney and its cells are invading the renal tubules.

insofar as more than half of them occur in individuals younger than fifteen years of age. There is often disagreement among pathologists as to whether a tumor of the adrenal cortex is an adenoma or a carcinoma. Invasion through the capsule and the presence of many mitotic figures are indubitable evidence of the fact that malignant disease is present. Abnormal physiologic changes may be present for years before the tumor is discovered, which suggests slow growth initially. Rappaport found that one-fourth of these patients showed some degree of cortical atrophy on the opposite side. All patients having an adrenal cortical tumor should be protected by cortisone or hydrocortisone supportive therapy during and following the removal of the tumor. Tumors producing virilism are less likely to cause atrophy of the opposite adrenal gland.

Both adenoma and carcinoma of the adrenal cortex may produce Cushing's syndrome. The incidence of malignancy has been reported as being higher when the tumor causes the mixed syndrome with elements of both virilism and Cushing's syndrome. The highest incidence seems to be in persons in the third and fourth decades of life. The majority of these tumors are found in females and it is to be remembered that Cushing's syndrome, due to hyperplasia of the adrenal cortex, is also much more common in women than in men. The physiologic autonomy of the tumor may be studied by efforts at inhibition with cortisone therapy or by efforts at stimulation with ACTH. These tests may be helpful with reference to prognosis.

Feminization in males is extremely uncommon, especially in adult males. It is characterized by gynecomastia, testicular atrophy and impotence. Wilkins reported a series of six instances, all of which resulted from adrenal cortical tumors. In such cases, clinically, it would be important to study if possible the urinary estrogen, 17-ketosteroid and androgen excretion.

MANAGEMENT OF HYPERADRENOCORTICISM

Medical therapy of Cushing's syndrome has been directed at adrenocortical inhibition. This has been most successfully carried out with cortisone acetate, but the improvements are incomplete and temporary. The administration of testosterone propionate has been of some help in improving protein metabolism. Pituitary irradiation in the treatment of Cushing's syndrome has been re-

viewed by Sosman. About 50 per cent of the patients treated underwent at least a partial remission, but in only one-sixth of those treated did the remission persist. Pituitary irradiation should not be used unless all physiologic tests indicate that the disease is due to adrenocortical hyperplasia, for in one-fourth of the patients having Cushing's syndrome, malignant tumors are present. The therapeutic procedure of choice in Cushing's syndrome, regardless of the adrenocortical lesion present, is the surgical removal of hyperfunctioning adrenal cortical tissue, which consists of resection of unilateral, rarely bilateral, tumors and total or subtotal adrenalectomy in patients with bilateral adrenal cortical hyperplasia. The following points in the surgical management of hyperadrenocorticism deserve emphasis.

Recently, adrenocortical surgery has been made possible by the availability of adrenocortical hormones. It is necessary that all patients subjected to the removal of adrenocortical tissue be adequately prepared preoperatively and supported postoperatively by careful observation and adequate hormonal replacement therapy.

Cortisone acetate, 100 mg. given intramuscularly, should be given twelve hours and two hours before surgery. Hydrocortisone should be administered intravenously continuously, at a rate of about 100 mg. per four hours, during the operation and immediately thereafter. Hydrocortisone may be continued postoperatively by constant intravenous drip at a rate of 100 mg. per eight hours. An alternative schedule which may be used would consist of cortisone acetate, 100 mg., given intramuscularly every eight hours, the day of operation and the first postoperative day.

The dosage of cortisone acetate is gradually diminished 25 mg. per dose after the third postoperative day. This reduction must be carried out slowly and carefully, according to the state of the patient who is recovering from the hyperadrenocortical state. Careful study of electrolyte balance, weight, carbohydrate metabolism and kidney function must be pursued throughout the immediate postoperative period.

The most expert medical opinion must be obtained with reference to the use of the salt-retaining hormones, such as fluorohydrocortisone and desoxycorticosterone acetate. A profound increase in excretion of sodium chloride may occur within the first ten days after bilateral total adrenalectomy and must be combated with adequate amounts of salt.

as well as the salt-retaining hormones. Adrenocortical insufficiency is manifested by the onset of headache, weakness, malaise, lassitude, nausea, vomiting and hypotension.

When an adrenal cortical tumor has been found and located preoperatively, unilateral adrenalectomy is performed. When a tumor has not been located by preoperative study, the patient is prepared for bilateral exploration. Since the surgical hazards are less on the left than on the right, exploration of the left adrenal gland is usually undertaken first. Simultaneous exploration of both sides can be carried out on patients who are not tremendously obese. Exploration of the opposite side is always desirable, irrespective of the gross characteristics of the visualized gland. If obvious adrenal cortical atrophy is present, a hyperfunctioning tumor on the opposite side is very likely.

If the adrenal cortices appear hyperplastic or physiologically hyperactive, bilateral adrenalectomy is indicated. Poutasse and Higgins reported the finding of bilateral adrenal cortical atrophy and the presence of an ectopic hyperfunctioning adrenal cortical lesion.

Bilateral adrenalectomy is the procedure of choice for adrenal cortical hyperplasia. If a tumor is found, the tumor and the entire adrenal gland on that side are removed. In the majority of patients, a single-stage operation with exploration of both sides can be carried out. However, if at the time of exploration it is apparent that the patient is not able to undergo a bilateral exploration, the performance of a unilateral adrenalectomy is the procedure of choice if the gland is abnormal.

Every effort is directed preoperatively toward the gaining of maximal renal and cardiorespiratory function. A plastic cannula is placed in the antecubital or internal malleolar vein preoperatively for the continuous administration of fluids, blood, hormones and pressor substances as necessary. The intravenous catheter should be removed within forty-eight hours because of its tendency to cause thrombophlebitis. Pentothal sodium induction followed by intratracheal nitrous oxide-ether anesthesia has been quite satisfactory. However, in very poor-risk patients, a continuous spinal anesthesia has been very efficacious. These patients must be watched continuously during the first twenty-four hours after operation. Every measure is instituted to forestall pulmonary and vascular complications: turning every two hours, deep-breathing exercises; dorsiflexion exercises of the feet; elevation of the foot

of the bed; use of elastic stockings prior to and after operation; and utilization of ambulation, avoiding the sitting position, as soon as reasonable.

Priestley and Cahill have advocated subtotal adrenalectomy. In our experience, it seems that bilateral total adrenalectomy is a preferable procedure for bilateral adrenal cortical hyperplasia. Subtotal adrenalectomy carries certain possible disadvantages. Relapse may occur in approximately 10 to 20 per cent of patients because of recurrent hyperplasia when an adequate remnant has been left. The state of the adrenal cortical remnant is unknown and adrenal insufficiency has occurred in approximately 50 per cent of patients so treated when reliance has been placed on this to maintain survival. The possibility that stress may precipitate an adrenal crisis, because there is not sufficient adrenal tissue to meet the hormonal demands, remains a real possibility. All of these patients have to be instructed with regard to meeting stress by an increased ingestion of hormones, such as cortisone acetate.

The results of adrenalectomy for hyperplasia or tumor of the adrenal cortex are very dramatic, but each patient has to go through a period of many months of adjustment to the new hormonal status. Careful observation during this period is very necessary. Susceptibility to infection must be guarded against and the patient's activities carefully regulated. In patients having virilism, hirsutism is very slow to change. Hypertension usually subsides but may persist, according to whether the vascular changes are irreversible. Osteoporosis is characteristically slow to heal. A dramatic improvement in diabetes may occur, but this also may be gradual in improving. Menses may be resumed within one month after removal of an adrenocortical tumor. Improvement in the skin, striae and hemorrhagic tendencies occurs within a few months. The mental status of the patient is usually markedly improved along with appetite and strength. The prognosis of patients having these disorders of the adrenal cortex has been tremendously changed as a result of the availability of adequate hormonal substitution therapy, which has made possible surgical removal of the adrenal glands and cure of the disorder.

ADRENOCORTICAL RELATIONS TO HYPERTENSIVE VASCULAR DISEASE

It is well known that adrenal cortical insufficiency is associated with hypotension and that the development of Addison's disease in patients with pre-existing hyperten-

Figure 11 The urinary sodium excretion in a man, aged thirty-four years, with malignant hypertension and intractable heart failure, before and after bilateral total adrenalectomy. This sodium excretion has been a striking measurable physiologic benefit derived in certain patients having malignant hypertension pursuant to total adrenalectomy

sion is usually accompanied by a fall in blood pressure to normal or subnormal levels. Hyperadrenocorticism and pheochromocytoma are each associated with elevation of the blood pressure. It is also known that ACTH is tolerated poorly by the hypertensive patient. Goldblatt has shown that experimental renal hypertension is not maintained in the absence of the adrenal glands. The administration of excessive amounts of desoxycorticosterone acetate to the addisonian patient who has had pre-existing hypertension will result in the return of hypertension. The above evidence that the adrenal cortex is involved in the maintenance of hypertension has led, since the advent of cortisone, to an investigation of the effects of adrenalectomy in patients with hypertensive vascular disease. The description of primary aldosteronism by Conn has further enhanced the interest in adrenocortical relations to hypertension.

Green found an improvement in patients with hypertension and those with diabetes after subtotal adrenalectomy. It was later shown by Thorn that the hypertensive patient not only could survive, but could lead an active existence, after total adrenalectomy. On the basis of experience gained in the last five years, the following conclusions

concerning the selection and maintenance of patients with severe hypertensive vascular disease may be made:

Complete and subtotal bilateral adrenalectomy are relatively safe procedures in properly selected patients. After total adrenalectomy, patients can be safely maintained on adequate substitution therapy which includes cortisone and appropriate doses of desoxycorticosterone acetate, or its equivalent, with additional supplementary sodium chloride depending upon the individual demands.

Though the chronologic age of the patient is not a critical factor, the physiologic age of the patient's vascular disease and the degree of reversibility of it are definite critical factors. Advanced coronary and cerebral arterial disease greatly enhances the hazard of adrenalectomy. Advanced renal vascular disease and renal insufficiency without exception are contraindications to adrenalectomy.

Adrenalectomy is ineffective in reducing arterial blood pressure unless some degree of adrenal cortical insufficiency is produced. However, regression of advanced coronary, renal or cerebrovascular arterial disease has not occurred, even though lowering of blood pressure has resulted.

The outstanding measurable physiologic benefit derived from total adrenalectomy in patients with hypertension has been the increased urinary excretion of sodium (Fig. 11) and water which occurs and significantly diminishes the total body sodium. This result has been of particular benefit in patients with intractable congestive heart failure (Fig. 12). Such a reduction in total body sodium is not a guarantee that blood pressure will fall and, in fact, a marked reduction in blood pressure in the presence of advanced vascular disease is not desirable. Patients having advanced irreversible vascular disease may suffer with cerebral anemia and diminution in renal function as a result of such reduction in blood pressure.

It seems that the simultaneous performance of sympathectomy may improve the effects of total or subtotal adrenalectomy in selected patients with hypertensive vascular disease.

On the basis of a series of patients with severe hypertensive vascular disease subjected to total adrenalectomy, severe angina pectoris, electrocardiographic evidence of advanced coronary artery disease and severe renal insufficiency are contraindications to the operation. In fact, all patients having a blood urea nitrogen of more than 40 mg. per 100 cc. have been made worse by adrenalectomy.

Continuous spinal anesthesia has been the anesthesia of choice for this procedure in these patients. The prone position allowing

a simultaneous bilateral exposure of both adrenals is desirable and is utilized in all patients who are not too heavy or obese. Exposure of the left adrenal is obtained by resection of the twelfth rib and it is desirable on the right side to get a wider field of exposure by resecting the eleventh rib. The prone position has the advantage of not changing the patient's position during the operation. If the posterolateral approach is used, a gradual change in position is carried out as severe hypotension may be precipitated if this is performed suddenly. At the termination of the operation the patient is carefully turned on the back and remains on the operating table in the recovery room for at least two hours in order to insure circulatory equilibrium. Disregarding these precautions may precipitate a profound cardiovascular collapse and even cardiac arrest.

The best results have been obtained in those patients suffering from congestive failure which has not responded to all forms of medical therapy. At the same time these patients must have fairly good renal function. In a series of twenty patients with varying degrees of hypertensive vascular disease, more than 50 per cent obtained some improvement pursuant to total adrenalectomy. None of these patients had hypokalemic alkalosis or histologic evidence of adenoma causing Conn's syndrome of primary aldosteronism. This improvement was maintained for more than six months in ten patients and in six of these patients the im-

CHANGES IN HEART SIZE FOLLOWING BILATERAL ADRENALECTOMY IN HYPERTENSION

W.C. § 36

Figure 12. Cardiac roentgenograms of the patient described in Figure 11 showing reduction in size of cardiac silhouette following total adrenalectomy. Over a period of four and a half years clinical improvement has been commensurate with the marked changes herein illustrated.

provement was maintained for more than four years. The improvement for the most part seemed to be based on the increased urinary excretion of sodium and water. Mental equanimity and better adjustment to environment were manifestations of psychologic improvement. The causes of death in the fifteen patients who died in this group were myocardial insufficiency in two, uremia in four, congestive failure in one, cardiac arrest in one, adrenal cortical insufficiency in two, carcinoma of the prostate in one, rupture of an aneurysm in one and cerebrovascular accident in three.

THE ADRENAL CORTEX IN THE TREATMENT OF CANCER OF THE PROSTATE AND BREAST

The endocrine control of the growth of the prostate and breast has been known for many years. In 1896, Sir George Beatson appreciated that carcinoma of the breast could be influenced by the secretion of the ovaries and he obtained a limited remission of the disease by performing oophorectomy. This operation was replaced by irradiation sterilization and it was not until recent years that it was appreciated that cessation of the menses did not necessarily mean that the secretion of estrogens had stopped. Surgical sterilization is the only certain method of stopping ovarian estrogen production. In 1893, White suggested removal of the testes for prostatic enlargement and, in 1896, Cabot reported on this method of treatment. It remained for Huggins, in 1941, to report his epoch-making discovery of response of cancer of the prostate to castration and the administration of estrogens. In 1945, Huggins and Scott reported bilateral adrenalectomy for cancer of the prostate which had reactivated after previous response to castration and estrogens. Some improvement was noted in these patients, but they all succumbed to adrenal cortical insufficiency. When cortisone acetate later became available, it was demonstrated that not only did the patient survive, but also he could lead an active existence after bilateral total adrenalectomy. An intensive study of the efficacy of this new attack on reactivated cancer of the prostate and breast has been carried out by Huggins and other investigators. At the same time, the value of adrenocortical inhibition by means of orally administered cortisone acetate prior to adrenalectomy was utilized after it had been demonstrated that diminished function of the adrenal cortex could be accomplished in this manner. Improvement of

patients having carcinoma of the prostate and of patients having carcinoma of the breast has been observed following cortisone inhibition of the adrenal cortex by a number of observers. Further investigation of the effects of adrenocortical inhibition with cortisone acetate and with fluorohydrocortisone is being continued.

Hormonal studies before and after castration have shown a marked reduction as a result of this procedure in the excretion of androgens. This was measured biologically. However, a significant excretion of androgen can be measured biologically after castration and this androgen excretion is further greatly diminished by total adrenalectomy. The administration of ACTH to patients after castration has shown a marked rise to occur in androgen excretion to much higher levels than were demonstrated in the resting state before orchiectomy. This concretely supports the assumption and studies of Huggins and Scott that the adrenal cortex is the source of extragonadal androgens which may play a role in the reactivation of cancer of the prostate.

At the Peter Bent Brigham Hospital a study of adrenalectomy for reactivated cancer of the prostate has been conducted during the past five years. The patients have all been in a terminal state from incurable cancer which has either failed to respond to other methods of therapy or has responded previously only to become reactivated at a later date. The patients chosen for treatment by adrenalectomy are now selected on the following bases. A previous response to castration and estrogen therapy has occurred, the local lesion or its metastases have subsequently reactivated, the patient having the neoplasm in its reactivated state should show a response to the administration of cortisone acetate over a period of weeks or months, and for the relief of unremitting pain.

If the response to castration and estrogen therapy lasted a year or longer, the prognosis following adrenalectomy is better because a more susceptible tumor is probably present.

Some patients have shown improvement for one to two years with cortisone therapy after a relapse following orchiectomy and estrogen therapy.

The principles of management previously outlined before and after operation are followed. The patients being treated by adrenocortical inhibition with cortisone acetate prior to operation receive 100 mg of this hormone daily for seven to ten days and the dose is gradually diminished to 50 mg. per

day, which is the maintenance dose until recurrence of symptoms requires increasing the dose. It is at this time that the operation of adrenalectomy is considered for that individual.

The adrenal glands secrete estrogens and therefore may also be responsible for maintaining and spreading carcinoma of the breast. Because of the unpredictable effect of bilateral adrenalectomy on the progress of carcinoma of the breast, as well as the morbidity and the mortality, this operation should be reserved for those patients in whom all other forms of treatment, both surgical and hormonal, have been tried. Present results indicate that this operation may be helpful in the patient who has bone pain due to skeletal metastases, visceral metastases with pulmonary deposits, secondary skin nodules, or large primary lesions. The operation is contraindicated in the presence of pleural effusion and/or underlying lymphangitis carcinomatosa, cerebral or hepatic metastases or renal failure.

The benefits to be derived from oophorectomy should be evaluated before proceeding to the drastic stage of total adrenalectomy. The response of the patient to adrenocortical inhibition with cortisone acetate should be judged also prior to this procedure. Inhibi-

tion by means of medical therapy should be continued as long as the patient is showing improvement.

RESULTS OF ADENALECTOMY FOR REACTIVATED CANCER OF THE PROSTATE

Relief of constant pain has been the most dramatic and frequently that benefit has been derived from cortisone acetate therapy and from total adrenalectomy for carcinoma of the prostate. A careful study of fifteen patients with reactivated carcinoma of the prostate for whom adrenalectomy was used as a final effort in treatment has been made. Eleven of these had persistent pain and six of them gained relief for periods of six to eighteen months. Decrease in the size of the pelvic mass of tumor was striking in one patient and improvement was obtained for forty months. Arrest of the growth of a large pelvic mass of prostatic cancer with definite decrease in size over a period of a year was accomplished in another patient. Improved micturition occurred in four patients. Definite decrease of the serum acid phosphatase (Fig. 13) has been observed in three patients and roentgenographic evidence of calcium deposition in osseous metastases has been observed in three patients following

Figure 13 Chart of the serum acid phosphatase determinations of a patient having widespread cancer of the prostate. Reactivation of the disease occurred a few months after orchiectomy and estrogen therapy with a rise in serum acid phosphatase. Both clinical improvement and fall in acid phosphatase occurred with cortisone therapy consisting of 100 mg given daily for two weeks. Bilateral total adrenalectomy was then done; the improvement was maintained and no rise in acid phosphatase occurred for six months, after which the neoplasm again reactivated and death ensued in a few weeks. This case graphically illustrates an effect on the neoplastic cell by changes in hormonal environment regarding androgens, estrogens and corticoids.

total adrenalectomy. With relief of pain, there is improvement of appetite, improved nutrition and a corresponding improvement in anemia. The patient showing a response to adrenalectomy is expected to have a decrease in calcium excretion and an early increase of alkaline phosphatase of the blood serum. Healing of pathologic fractures has been observed in two patients after total adrenalectomy. This form of therapy must be regarded as palliative at best and the results in the treatment of cancer of the prostate have not been as impressive as those obtained in the treatment of cancer of the breast. It must be emphasized at this time, that, on the basis of the histologic picture alone, the subsequent biologic behavior of the tumor, either of breast or prostate, cannot be accurately predicted. The highly undifferentiated anaplastic and especially scirrhous types of carcinoma do not seem to respond as well to hormonal therapy as does adenocarcinoma.

RESULTS OF ADRENALECTOMY FOR CANCER OF THE BREAST

In adrenalectomy for cancer of the breast, the objective and subjective improvement may not necessarily be commensurate. As in cancer of the prostate, subjective improvement may be very dramatic with relief of pain within twenty-four to forty-eight hours after the operation. The objective improvement includes the decrease or even disappearance of pulmonary metastases, the decrease of pleural effusion or the diminution in size of the primary lesion. Evaluation of the objective results shows that 25 per cent are excellent, 50 per cent of the subjects are improved and 25 per cent are unaffected. The subjective results are quite similar. It is not possible to select accurately those patients who will show an excellent response. However, it seems that those patients who show a good response to adrenal cortical inhibition are more likely to get a good result pursuant to bilateral adrenalectomy than those who do not show such a response. The results have been better and more prolonged in the use of this therapy for cancer of the breast than for cancer of the prostate. The really significant fact is that both types of tumor have been affected by this method of hormonal therapy and it is indicated that further efforts be made to select more accurately those who will be benefited by such treatment. The striking diminution of calcium excretion following adrenalectomy has been emphasized by Pearson and serves

as a reliable index of improvement in the treatment of cancers of breast and prostate.

Prednisone (Meticorten) has been used effectively for adrenocortical suppression and has been accompanied by fewer side effects than cortisone acetate. Such medical therapy may give good results for periods up to two years in reactivated cancer of prostate and breast.

TUMORS OF THE ADRENAL MEDULLA

The adrenal medulla, though not essential for life, plays an important part in stress, owing to the liberation of epinephrine. It arises from primitive cells (sympathogonia) which migrate to and penetrate the adrenal cortex in about the seventh week of fetal life. Because of their common origin, both the sympathetic ganglia and the adrenal medulla are the seat of similar tumors. The most common of these is the neuroblastoma or sympathicoblastoma, less common are the pheochromocytoma, or chromaffinoma, and the benign ganglioneuroma.

Since the work of Cannon, an additional medullary hormone, norepinephrine, has been identified, existing with epinephrine in the normal gland in a ratio of 1:4. The presence of norepinephrine has been demonstrated in the adrenergic nerves of cattle as the probable chemical mediator of the sympathetic nerve impulse. The effects of medullary stimulation in the normal subject are due mainly to epinephrine, that is, increase in cardiac output with resulting hypertension, diminished peripheral resistance, increase in glycogenolysis, increase in oxygen consumption, increase in muscle and splanchnic blood flow and decrease in skin blood flow with resulting pallor. Norepinephrine, on the other hand, in equivalent doses produces hypertension due to increase in peripheral resistance without the other metabolic effects seen with epinephrine. With large doses, the effects of the two drugs tend to overlap.

Pheochromocytoma. This tumor arises from chromaffin cells of the adrenal medulla, or other parts of the sympathetic system, and is the only secreting tumor of the medulla. About 10 per cent of these neoplasms are malignant and show a tendency toward early widespread metastases. About 10 per cent are bilateral and more than 15 per cent are extra-adrenal in origin.

The syndrome produced by these tumors is characterized by sustained or paroxysmal hypertension. In Smithwick's series of 1000 cases of lumbodorsal symp- tomy for

hypertension, there was a 0.5 per cent incidence of pheochromocytoma. Elevation of the basal metabolic rate and hyperglycemia may occur. About 25 per cent of the patients show acute paroxysms of hypertension with sudden, severe rises in blood pressure, sometimes to levels in the systolic pressure of 300 mm. of mercury. Headache, palpitation, anxiety, tachycardia, pallor and hyperhidrosis are of frequent occurrence and visual blurring, epigastric and precordial pain, nausea and vomiting may also occur. The attacks may last minutes or days and tend to become more frequent as time elapses. Paroxysms may be induced by pressure over the tumor or by emotional upsets. All of the complications of severe hypertensive vascular disease may occur. An attack may terminate in a fatal shocklike state of hyperpyrexia and hypotension, or death may occur from pulmonary edema, ventricular fibrillation or cerebral hemorrhage. The persistent form of hypertension may be indistinguishable from essential hypertension on clinical grounds. In a few instances, hypermetabolism and hyperglycemia have been present without hypertension.

Since both epinephrine and norepinephrine are present in varying amounts, the quantitative chemical composition of the tumor determines the clinical picture, as a general rule. Though they differ markedly when used in small doses, the two hormones tend to produce similar effects when present in large amounts. Tumors which elaborate large amounts of norepinephrine, or have a predominant amount of epinephrine, tend to produce hypertension, tachycardia, hyperhidrosis, hypermetabolism and frequently hyperglycemia. Tumors which are small and contain, for practical purposes, only norepinephrine closely mimic, in their effects, essential hypertensive vascular disease. In some patients, sustained hypertension has been observed in the absence of active secretion of medullary products in intervals between paroxysmal discharges of the medulla. Elevated blood pressure has also been noted to persist after removal of all hyperactive chromaffin tissues, apparently because of a process initiated by long-continued hypersecretion.

The plain film of the abdomen, together with pyelography, has been helpful in demonstrating the presence of a suprarenal mass in a number of instances. Presacral injection of carbon dioxide into the retroperitoneal spaces has been helpful in outlining tumors in the suprarenal area, but false positive results may be obtained and small tumors can-

not be seen. In some patients, a mass is palpable within the abdomen. Pharmacologic testing agents have been of great help in the diagnosis of these lesions. These are of two groups: the adrenergic blocking agents—benzodioxane and Regitine—and the provocative agents—histamine, Mecholyl and tetraethylammonium chloride. Of these, benzodioxane, Regitine and histamine have proved to be of the greatest value. Determination of urinary catecholamines, as a measure of adrenal medullary activity, appears to hold promise for a more accurate diagnosis of these tumors.

Surgical removal by the most direct route is the desired treatment. Because of the increased risk of cardiac arrhythmias in the presence of high circulating levels of epinephrine, cyclopropane and ethyl chloride should not be used as anesthetizing agents. Likewise, anoxia should be avoided because of its stimulating effect on the adrenal medulla. A general exploration of the abdominal cavity is of great value in view of the variability in location and the multiplicity of these tumors. A transperitoneal approach gives the opportunity for a general exploration and is especially useful when the location of the tumor is in doubt. Tumors arising outside of the abdomen are dealt with according to their particular location. When a well-localized neoplasm is clinically diagnosed in the adrenal area, the transcostal approach provides for a direct attack on the tumor and its blood supply.

Paroxysmal rises in blood pressure during operation and profound hypotension post-operatively constitute the most serious complications. The former is combated by the use of adrenergic blocking agents and the latter by the employment of vasoconstrictive agents such as epinephrine, Neo-Synephrine and norepinephrine. The possible occurrence of adrenal insufficiency following surgery should be anticipated and the patient treated promptly.

Neuroblastoma Sympatheticum. This is the most common malignant tumor occurring in infancy and early childhood and, in spite of its highly malignant character and tendency toward early, widespread metastases, much has been done to improve prognosis in these patients. About 57 per cent of the neoplasms are intra-abdominal in location.

In a few instances, a spontaneous cure has been noted due either to hemorrhage and necrosis of the tumor or to conversion of the neoplasm into a well-differentiated, benign ganglioneuroma.

A large abdominal mass is often palpable.

Anemia, weakness, weight loss, evidence of metastases by x-ray and physical examination, pain due to involvement of nerves or adjacent structures, and displacement of the kidney downward and laterally without invasion of the renal substance are all frequently seen. Metastases spread by way of lymphatics to regional lymph nodes and by way of the blood stream to bones, liver and other organs. Plain roentgenograms of the abdomen and either intravenous or retrograde pyelography, along with survey films of the bones and chest, are of help in establishing the diagnosis.

A short, well-organized period of study and supportive therapy are the appropriate measures. A transabdominal or combined flank and abdominal approach with resection of the eleventh and twelfth ribs is used. If the tumor is not completely resectable, as much as possible is removed and postoperative x-ray therapy given. These tumors are generally very radiosensitive and the combination of surgery and x-ray treatment started immediately following operation yields a cure rate which is much better than that previously obtained by surgery alone. In a few patients, roentgen ray therapy alone has been responsible for cure.

THE SPLEEN

By ROBERT M. ZOLLINGER, M.D.,
and ROGER D. WILLIAMS, M.D.

ROBERT MILTON ZOLLINGER was born in Ohio and was educated in The Ohio State University and its Medical School. After receiving his M.D. in surgery in Boston and Cleveland, he served as its Professor of Surgery.

He is associated with the Department of Surgery at The Ohio State University as an Assistant Professor and received his education in medicine at Duke University. His surgical training was received at The Ohio State University where he also did graduate work in the Department of Pathology.

The spleen continues to be one of the most interesting yet least understood organs within the abdomen. Since the left upper quadrant of the abdomen is a relatively silent area, most physicians think of the spleen only in terms of splenomegaly or traumatic rupture. The spleen, however, is often involved in many generalized systemic disease processes and primary splenic abnormalities may produce widespread effects. Abnormalities of splenic physiology which have been more clearly delineated in recent years are not necessarily associated with splenomegaly. The unwary physician may be misled unless he is familiar with the many diseases of this organ.

The changing concepts of splenic function make difficult the classification of splenic diseases under categories wherein there may be indication or contraindication for splenectomy. It may be assumed that trauma usually presents the most common indication for splenectomy in the United States. Whereas some consider surgery of no value

in erythroblastic anemia and leukemia, many reports of the favorable results of splenectomy in certain cases tend to refute earlier impressions. Certainly, no set rules regarding surgery can substitute for competent hematologic evaluation of patients with splenic disease.

SURGICAL ANATOMY

Lying beneath the left ninth, tenth and eleventh ribs, the spleen is rarely palpable unless enlarged. In the adult it averages approximately 11 by 7 by 4 cm. in size and weighs approximately 200 gm. It is usually shaped like a large coffee bean and often has a notch along its anteromedial border. The medial concave surface is bordered by the stomach to which the upper pole may be closely attached. The lateral convex surface lies against the left diaphragm and kidney.

The peritoneal attachments of the spleen are of great surgical importance. Three of these form ligamentous structures: the

Figure 1. The spleen and its relations to the stomach, colon and pancreas. An opening has been made through the gastrosplenic ligament showing a suture being passed beneath the splenic artery proximal to the splenic pedicle.

which course the arteries and veins (Fig. 1). The *presplenic fold*, coursing from the lower pole and hilum of the spleen to join the gastrosplenic ligament, is thin and rarely very vascular. The *gastrosplenic fold* extends as a double peritoneal layer from the splenic hilum to the greater curvature of the stomach. Through these layers course the short gastric arteries and veins which form large collaterals when there is impairment of flow in the splenic artery or vein. This ligament is greatly shortened as the superior hilum lies in close contact with the stomach. The *splenorenal ligament*, another double peritoneal fold, stretches from the tail of the pancreas to the splenic hilum and contains the splenic artery and vein. Several smaller peritoneal attachments between the spleen and diaphragm and the spleen and colon may be prominent when the spleen is enlarged or there is portal venous hypertension.

The splenic artery, the largest branch of the celiac axis, follows an irregular course over the superior border of the pancreas to

divide into several branches near the hilum. Of the four branches commonly noted, three supply the spleen and two supply the greater curvature of the stomach. The superior and inferior terminal arteries and the superior polar artery all give branches into the spleen and the latter, in addition, gives off the short gastric vessels to the fundus of the stomach. The gastroepiploic artery branches off to the greater curvature of the stomach. The splenic vein follows a similar course to the artery, except that its course is usually inferior and straighter than that of the artery, being frequently partially embedded within the pancreas. The lymphatic drainage of the spleen follows the vessels along which there may be numerous lymph nodes.

INTERNAL ANATOMY

The internal anatomy is less readily defined. The larger arteries which enter at the hilum branch off into the trabeculae, the fibromuscular tissue framework of the spleen. Several trabeculae may form a small,

almost microscopic, lobule. The trabecular arteries branch off into a zone of lymphoid tissue, the malpighian body. Continuing from this lymph follicle are the penicillate arteries which communicate either directly, through capillaries, or indirectly, through the splenic sinuses, with the venules. Direct communications through multiple preformed channels have been noted. More recently, studies well documented by photographs and movies strongly support a combined open and closed system where blood flows from the arteries into both pulp spaces and venous channels.

The splenic pulp is composed of sinuses and several types of cellular elements. The pulp contains lymphocytes, granulocytes and erythrocytes. There are numerous branching strands of lymphoid tissue, known as the cords of Billroth. The sinuses occupy most of the pulp and are lined by a reticular network which becomes continuous with pulp partitions. Within this network are amebic phagocytic cells. In the congested spleen, the line between sinus and parenchyma may be poorly defined and changes which occur with certain splenic dysfunctions are somewhat inconstant.

PHYSIOLOGY

Normal physiologic functions of the spleen are of much less importance than splenic hyperfunction. The spleen is important, primarily, as a large part of the reticuloendothelial system and, secondarily, because of its position in the portal venous circulation. Since the spleen is not essential to life, its functions being readily assumed by the remainder of the reticuloendothelial system, normal function has been difficult to evaluate.

Several functions may be ascribed to the spleen. It may act as a reservoir, yielding increased quantities of blood during stress or exercise. Gradual changes in volume take place under normal situations. In the embryo the spleen takes part in blood formation and although this function ceases after birth, it may be taken up again under demand (extramedullary hematopoiesis). Lymphocytes continue to be formed throughout life. Blood destruction also occurs in the spleen, as in all reticuloendothelial tissue. Although phagocytosis is probably insignificant, fragmentation of red cells during periods of relative splenic congestion probably occurs. There is some evidence that the spleen has a regulatory action to increase red cell fragility. The spleen plays an active part in defense

mechanisms which include the formation of antibodies.

Several studies suggest that the spleen may have an *endocrinologic function*. The spleen has been considered a regulator of bone marrow, controlling the emission of its various elements by a humoral mechanism. Some splenic extracts stimulate and others depress the bone marrow. Serum from patients with cytopenias considered due to hypersplenism or dyssplenism have produced similar cytopenias when injected into a normal individual. These functions are probably cytoimmunologic and often can be suppressed by adrenocorticotropin (ACTH) and cortisone. The release of a vasodilator substance, in combination with peripheral cytologic changes resulting from stress, has been considered due to a substance called "splenia" by Ungar. This response to stress is inhibited by splenectomy.

ANOMALIES

Except for accessory spleens, anomalies of the spleen are rare. Congenital absence and marked lobulation of the spleen have been noted but are of no clinical importance.

Accessory Spleens. An accessory spleen consists of a separate encapsulated mass of splenic tissue which has probably been pinched off from the main splenic mass during embryologic development. It has been suggested that many occur in the embryo but disappear after birth unless perpetuated by increased demand in such diseases as congenital hemolytic icterus or thrombocytopenic purpura. They occur most commonly in the splenic hilum, the splenic pedicle or tail of the pancreas, the gastrosplenic ligament and the gastrocolic ligament. Rarely, they are found over the left kidney or even in the scrotum. Accessory spleens are reported in 18 to 30 per cent of patients undergoing splenectomy. They number from one to five or more and vary from a few millimeters to several centimeters in size. Although they have the same gross appearance as the spleen, they are readily confused with lymph nodes. Often the accessory spleen not only has its own small artery and vein but also a separate pedicle.

When splenectomy is performed for hypersplenism, it is important to remove all accessory spleens since they may be the cause for continuation or recurrence of the disease. In the patient with a relapse of hypersplenic hematologic changes, suspicion of an overlooked accessory spleen may be confirmed by the injection of Thorotrast or diopaque

substance which localizes in the spleen, liver and other tissue of high reticuloendothelial content. The accessory spleen probably causes relapse of hypersplenism by its marked hypertrophy; however, in many cases of thrombocytopenic purpura, accessory splenectomy has not given great improvement.

ECTOPIC SPLEEN

Abnormal position of the spleen is quite uncommon and is due to either rare congenital elongation of the splenic pedicle or general abdominal wall relaxation with or without visceroptosis. This condition occurs most often in middle-aged women, and the spleen is almost invariably enlarged.

The diagnosis of ectopic spleen may be extremely difficult, particularly when the organ becomes fixed in the new position. Symptoms consisting of nausea, vomiting, constipation or a tugging sensation within the abdomen are variable and may not be present at all in the freely movable spleen.

The treatment of ectopic spleen is splenectomy. This may be an emergency procedure if there is torsion of the splenic pedicle.

TRAUMA

Splenic injuries are common and if rupture of the spleen is kept in mind, its diagnosis is not usually difficult. Rupture or contusion of the spleen should be considered in most automobile accidents of severity, particularly when the abdomen or left thorax is involved. Fractured ribs may direct attention to the underlying spleen, yet the association of rib fractures with splenic rupture occurs in only about one out of five cases. In children, rib fractures are even less common.

Classification of open or closed wounds serves little purpose. Most open wounds occur with war injuries and are usually obvious. Contusion or laceration of the spleen is more common, yet less readily diagnosed. Either contusion or rupture may follow a violent blow, however, rupture without obvious trauma may occur.

Two peculiarities of splenic rupture are often observed. The first of these is spontaneous rupture without a history of trauma, occurring usually in a soft, friable, diseased spleen. It has been reported to occur with malaria, typhoid fever, several of the lymphomas, Boeck's sarcoid and infectious mononucleosis. In addition, spontaneous rupture occurs even with a normal spleen although this is rare.

The second peculiarity of the spleen is its

tendency to secondary rupture at varying intervals following the episode of trauma. This phenomenon occurs in approximately one out of six cases, any time from one to thirty or more days after injury. Nearly 75 per cent take place during the first two weeks following trauma. The recurrence of rupture or hemorrhage may be due to continuous increase in a subcapsular hematoma or failure of the omentum or a clot to offer complete tamponade of the spleen.

The symptoms are those of blood loss into the peritoneal cavity. The signs may be minimal or marked. If the blood loss is great, weakness, abdominal pain and muscle spasm, either generalized or localized in the left upper quadrant, and depression of abdominal breathing are noted. Rebound tenderness is common and may be more noticeable than tenderness to palpation. Phrenic reference of pain to the left shoulder occurs in nearly three-fourths of the cases and is diagnostically significant. All symptoms may be overshadowed by shock and other bodily injuries. A palpable tender mass, fixed dullness in the left flank (Ballance's sign) or shifting dullness due to free blood in the peritoneal cavity is a less common finding.

Leukocytosis, with a white count of over 12,000, is of more diagnostic importance than is early anemia. With rapid hemorrhage, hemoconcentration may precede the lowering of hemoglobin or red blood cell count. Abdominal x-ray study may be of value, both in suggesting splenic rupture and confirming the presence of other injuries. The findings include elevation of the diaphragm; depression of the colon; medial and anterior displacement of the stomach gas shadow, occasionally with serration along its greater curvature, absence of the psoas shadow; absence of the left renal shadow, and usually a diffuse haziness in the left upper quadrant without a normal splenic outline. Finally, a peritoneal tap is readily performed utilizing a no. 20 or 18 needle and a 10-cc. syringe. If blood is encountered, the diagnosis of internal bleeding is confirmed and the possibility of splenic rupture strongly considered. A negative tap does not eliminate the diagnosis of splenic rupture.

The only safe treatment for splenic rupture is splenectomy which should be performed without hesitation. When the diagnosis is in doubt but there is strong evidence of intra-abdominal injury, exploratory laparotomy is justified. Suture of tears is not satisfactory. Whole blood should be made

readily available and usually one or more transfusions are required. Following splenectomy, complete exploration of the entire abdomen is an absolute necessity in order that the possibility of other intra-abdominal injuries may be eliminated.

The results of splenectomy largely depend upon the extent of other injuries. Nearly half of the patients with ruptured spleen have other injuries to the head, chest or extremities which detract from the diagnosis of splenic injury and increase mortality. Approximately one-third of the patients have other intra-abdominal injuries to the kidney, bladder or intestinal tract. Multiple injuries occur since the most common cause of splenic rupture is an automobile accident. If a ruptured spleen is the only significant injury, the mortality is low, when multiple injuries occur, mortality will depend upon the time and adequacy of treatment of all injuries.

HYPERSPLENISM

Several clinical entities in which there is a depression of one or more of the formed elements of the blood are considered to be due to splenic overactivity. Whether the spleen acts directly to produce an increased breakdown of peripheral blood elements, elaborates a humoral substance which affects the productivity of the bone marrow or produces antibodies which act on the cellular elements is subject to debate by hematologists. Regardless of the mechanisms of hypersplenism, the resulting decrease in red cells, platelets, white cells or all three of these elements produces well-known clinical diseases. These diseases are classified as *primary hypersplenism* if congenital, hereditary or of unknown cause, and as *secondary*

hypersplenism if they occur during the course of another chronic disease process.

Four clinical diseases comprise the syndrome of primary hypersplenism (Fig. 2). Depression of circulating blood platelets due to splenic overactivity results in essential, or primary, thrombocytopenic purpura. The destruction of red blood cells produces congenital hemolytic anemia. Primary splenic neutropenia and panhematopenia are two more recently recognized diseases, in which there is a depression of leukocytes (granulocytes) or all three of the formed elements of the blood. In all four of these disease processes, splenectomy effects excellent results.

Secondary hypersplenism produces identical cytopenias, but the splenic dysfunction develops secondary to another chronic disease. The primary chronic diseases include leukemia, Banti's disease, Gaucher's disease, Hodgkin's disease, the other lymphomas, tuberculosis, Boeck's sarcoid and other chronic infections. Secondary hemolytic anemia, thrombocytopenia, neutropenia or panhematopenia may occur as a complication during any phase of one of these chronic disease processes. Although splenectomy may produce dramatic remission of the hypersplenism and thereby lengthen life, the primary disease continues its course.

An accurate diagnosis is the prerequisite to good results in the management of hypersplenism. Splenomegaly, peripheral blood cytopenia and a hyperplastic bone marrow compose a triad which should cause the diagnosis to be considered. History and physical examination are important, toxic cytopenias are suggested by history. The spleen is usually but not always palpable, the larger spleens occur in patients with

3. PRIMARY SPLENIC NEUTROPENIA

4. PRIMARY SPLENIC PANHEMATOPENIA

Figure 2 Several mechanisms may occur whereby a decrease of blood platelets, red cells, white cells or all three elements by a hyperactive spleen produce four clinical disease entities, depending upon which element or elements are decreased.

secondary hypersplenism. Routine blood studies may suggest hypersplenism, but more specific studies are required to confirm the diagnosis in most instances. Bone marrow studies must be made and interpreted by a competent hematologist. A bone marrow hyperplasia of the specific element or elements which are decreased in the peripheral blood should be found.

The epinephrine (Adrenalin) test is of value in the diagnosis of hypersplenism when interpreted in the light of other hematologic findings. After a fifteen- to thirty-minute base line period, two peripheral blood studies are made following which 0.5 to 1.0 cc. of 1:1000 epinephrine is given subcutaneously. Repeated blood studies at ten-minute intervals are made and correlated with the period of maximum blood pressure rise which coincides with maximum splenic contraction. A marked rise in peripheral blood elements is considered suggestive of hypersplenism, but the test must be interpreted with caution.

Primary (Idiopathic) Thrombocytopenic Purpura. Primary hypersplenism, associated with reduced blood platelets and abnormal bleeding, has been called essential thrombocytopenic purpura, idiopathic thrombocytopenic purpura and Werlhof's disease. Clinical manifestations, due to pathologic bleeding, are the result of a combination of abnormal capillary permeability and a lowered blood platelet level. With an onset early in life, the disease may be continuous or intermittent.

One of three mechanisms responsible for the reduction of platelets is thought to be primary hypersequestration and lysis in the spleen. A second mechanism is responsible for abnormal platelet production in the bone marrow from a humoral substance liberated from the spleen. The production of thrombocytopenia in the normal individual by injection of serum from a patient with thrombocytopenic purpura, the occurrence of thrombocytopenic purpura in the newborn and the response of many patients with this disease to adrenocorticotropin (ACTH) and cortisone add weight to the contention of a number of recent investigators that immunologic factors are of great etiologic importance.

Recent reports show that idiopathic thrombocytopenic purpura occurs in two forms. One, an acute, usually self-limiting disease, occurring in infants and children, frequently develops spontaneous remission over a period of several weeks to a year.

Evidence for hereditary factors is inconclusive and there is nearly equal sex distribution. The other is a chronic disease, occasionally with temporary or incomplete remissions in young adults, but usually requiring splenectomy after failure of permanent responses to adrenocorticotrophic hormone (ACTH) or cortisone. Females are more commonly affected with this form.

Easy bruising, an otherwise asymptomatic rash, nosebleeds or menorrhagia may be the first symptoms. The signs and symptoms depend upon the severity of the thrombocytopenia. Although frequent ecchymoses may follow trauma in mild cases, spontaneous skin, mucous membrane, gastrointestinal or cerebral hemorrhages are usually associated with platelet levels well below 70,000. Menorrhagia is a common first symptom which probably is treated at its onset without diagnosis of thrombopenia since there are frequent associated gynecologic abnormalities. Intracranial hemorrhage presents a serious problem in approximately 10 per cent of cases.

The diagnosis is dependent upon the symptomatology and the hematologic findings. Splenomegaly is uncommon and when found suggests other diagnoses such as secondary hypersplenism due to leukemia, Hodgkin's disease or some chronic systemic infection. Purpura, or spontaneous hemorrhage, is found to be due to markedly lowered blood platelet levels. Bleeding time is prolonged, clotting time is normal and clot retraction delayed or absent. Demonstration of an abnormal coagulation mechanism can be made, however, by the finding of a defective prothrombin consumption. Reaction to the tourniquet test (Rumpel-Leede phenomenon), in which a tourniquet is applied to the arm for ten minutes at a pressure half-way between systolic and diastolic blood pressure, is positive, showing numerous petechiae of the skin. Differentiation can be made between purpura hemorrhagica and hemophilia by the history and a prolonged clotting time, normal clot retraction, a negative reaction to the tourniquet test and a normal platelet count in patients with hemophilia. Hyperplasia of the megakaryocytes of the bone marrow must be present. Erythroid hyperplasia is also usually present to a degree consistent with the anemia. This finding of marrow hyperplasia is of utmost value in differentiating essential thrombocytopenic purpura from other purpuras due to the effects of toxins, tumors or infections of the bone marrow.

The dramatic subsidence of bleeding and low mortality have made splenectomy the treatment of choice in most adult patients with this disease. Spontaneous remissions are common in childhood, however, and the results of splenectomy do not indicate an advantage over medical therapy. Adrenocorticotrophic hormone (ACTH) and cortisone decrease bleeding tendency by their effect on capillary permeability plus an elevation of platelet levels. They have been of great value in deferring surgery. In patients failing to respond to these drugs, and those with chronic thrombocytopenia which relapses after drug therapy is stopped, splenectomy is indicated.

Surgery should not be delayed in the face of continuously lowered platelet levels because of the danger of intracranial hemorrhage. Preoperative fresh whole blood transfusions have been recommended, not only as a source of platelets but also to raise the lowered blood volume found consistently in these patients. In those patients with inadequate platelet response to splenectomy, adrenocorticotropin (ACTH) or cortisone may be of value following removal of the spleen.

Primary (Congenital) Hemolytic Anemia. Of the several forms of hemolytic anemia, the spleen probably plays the most important role in congenital hemolytic anemia. This disease has been described under the terms congenital hemolytic jaundice, acholuric jaundice and spherocytic icterus, all of which point to the clinical features of anemia, jaundice without bile in the urine and the typical spherical characteristic of the red cells. Although spherocytosis is common with other forms of anemia, the familial tendency delineates this entity. Careful history and/or hematologic evaluation of several members of the family may be necessary to establish the diagnosis, since mild cases may be entirely asymptomatic. Despite the persistence of spheroidal cells with increased susceptibility to hemolysis, splenectomy is usually curative.

The symptoms vary markedly with the severity of the disease. One member of the family may have severe anemia, splenomegaly and jaundice, while all others have only the characteristic spherocytosis without significant anemia. Latent forms of the disease may become active any time between infancy and the fifth decade of life. Remissions and exacerbations are then common. Mild jaundice, weakness and malaise are the most common symptoms. These patients are not

actually sick, except when hemolytic crisis and acute severe exacerbation of hemolytic activity occur. Dull pain or dragging discomfort in the left upper abdomen is occasionally found and splenic tenderness with splenomegaly increases during exacerbations of hemolysis. Nausea and vomiting, abdominal pain and a rapid increase in jaundice are noted with a hemolytic crisis.

As with all jaundiced patients, the diagnosis depends upon an accurate history plus certain laboratory data. Confirmation of the familial nature of the disease is important. The peripheral blood shows microcytic anemia with 2 to 4 million erythrocytes per cu. mm and from 4 to 12 gm. of hemoglobin per 100 cc. Counts below 1 million occur with hemolytic crisis. Spherocytosis and a marked reticulocytosis (5 to 20 per cent) are invariably present. The spheroidal red cells show increased fragility with hemolysis in 0.7 to 0.5 per cent saline, as compared with 0.45 per cent for normal cells. The bone marrow shows an erythroid hyperplasia of a degree dependent upon the degree of anemia. Bone marrow studies are absolutely necessary to rule out other forms of anemia. In the indirect blood van den Bergh test, the value is elevated. There is an increase of urobilin in the urine and stool, but bile is absent in the urine (acholuric jaundice) while urobilin is increased. Splenomegaly is common, the spleen usually weighing 1000 to 1500 gm., but the spleen may not be palpable in patients having mild or asymptomatic anemia.

The only acceptable treatment is splenectomy. If the diagnosis is correctly established, the results of splenectomy are immediate and dramatic. Preoperative transfusions are contraindicated since the danger of producing hemolytic crisis is greater today than splenectomy in a moderately anemic patient. Once the splenic artery is ligated, blood replacement should follow. Although spherocytosis and increased red cell fragility are not changed, hemolysis ceases following splenectomy.

Primary Splenic Neutropenia. Neutropenia and granulocytopenia due to primary hypersplenism were first described in 1939. The decrease in white cells due to overactivity of the spleen and the response to splenectomy have been confirmed by numerous observers.

The symptoms are usually those of a recurrent or chronic infectious process. Oropharyngeal and skin infections may be

mittent fever. Infections respond poorly to the usual methods of therapy. In some cases, markedly severe anemia and mild jaundice have been noted. Splenomegaly is usually present and the large spleen may cause abdominal discomfort. Joint pains in some patients have suggested Felty's syndrome from which primary neutropenia must be differentiated.

The diagnosis is dependent upon the findings of neutropenia for which there is compensatory myeloid hyperplasia of the bone marrow. Positive reaction to the epinephrine test—splenic contraction with a significant temporary elevation of circulating neutrophils—is of diagnostic value. Anemia and mild thrombocytopenia may also occur in varying degrees. Care must be taken to rule out toxic neutropenias in which the bone marrow is not hyperplastic and shows myeloid maturation arrest.

Although splenectomy is the treatment of choice, the neutropenia usually runs a cyclic course and surgery may await an optimum peak in peripheral white cell count. If severe neutropenia persists, surgery becomes mandatory. Antibiotics are required to combat present infections and prevent operative wound infection. Whole blood transfusions are utilized to replace the consistently noted blood volume deficits and thereby lessen the surgical risk.

Primary Splenic Panhematopenia. The simultaneous occurrence of thrombopenia, neutropenia, and hemolytic anemia due to hyperactivity of the spleen has been delineated as a clinical entity called splenic panhematopenia. Although the degree of the various cytopenias may differ, their mechanism of development is considered similar.

Symptoms of panhematopenia vary, being somewhat dependent upon the severity of the specific cytopenia. Weakness, malaise, scattered recurrent infections, easy bruising, petechiae and jaundice are the most common symptoms. When platelet counts are markedly lowered, spontaneous mucosal hemorrhage ensues. Splenomegaly is a consistent finding. The differential diagnosis may be difficult, hypoplasia of bone marrow and secondary hypersplenism must be considered. A compensatory hyperplasia of all the cellular elements of the bone marrow must be found to confirm the diagnosis. Even then, lymph node biopsy may lead to the discovery of another systemic disease process, changing the diagnosis to secondary hypersplenism.

Splenectomy is indicated. The indications

and contraindications to preoperative transfusions, antibiotics, adrenocorticotropin (ACTH) or cortisone and the decision of optimum time for surgery are problems trying the judgment of a competent hematologist. Surgical results will depend upon the adequacy of preoperative evaluation.

Secondary Hypersplenism. During the course of certain chronic disease processes which involve the reticuloendothelial system, associated hypersplenism occasionally develops. This produces cytopenias identical with those already described under the various forms of primary hypersplenism. The typical features are those of the various specific blood cytopenias or panhematopenia with a definite compensatory bone marrow hyperplasia. Secondary thrombocytopenic purpura, hemolytic anemia, neutropenia and pancytopenia have all been recognized. Since complications of the hypersplenic cytopenias can be expected, splenectomy is indicated.

The chronic disease processes with which hypersplenism has been associated have been listed under the general remarks on hypersplenism. Secondary splenic anemia of the hemolytic type is the most common form of secondary hypersplenism. In a series of 471 patients with hypersplenism seen over a twelve-year period, 206 had secondary hypersplenism. This included 109 patients having secondary hemolytic anemia, thirty-five with secondary splenic neutropenia, thirty-five with secondary splenic panhematopenia and forty-one with secondary thrombocytopenic purpura.

The diagnostic criteria in secondary hypersplenism are similar to those of the primary form of this syndrome. Signs and symptoms vary widely and may be complicated by those of the primary disease. The spleen is almost invariably enlarged to a much greater degree than in patients having primary hypersplenism. Splenomegaly is due in large part to involvement in the primary chronic disease process.

If surgical mortality and morbidity are to be kept low, great attention must be given to preoperative preparation in these subjects. Owing to the nature of the diseases with which hypersplenism is associated, most of the patients are poor surgical risks. They are generally of an older age group, often with much deterioration resulting from the original disease. The principles of surgery include attention to details in the preoperative preparation with the establishment of optimum nitrogen balance, blood volume

levels and pulmonary reserve. Close cooperation with a hematologist is mandatory. Although splenectomy cannot be expected to affect the ultimate outcome in the chronic disease with which secondary hypersplenism is associated, the hematologic improvement following splenectomy, after adequate preparation, strongly justifies surgery even in many debilitated patients

ACQUIRED HEMOLYTIC ANEMIA

While the etiologic basis of primary and secondary hemolytic anemia is ascribed to a defect in the red cell and a selective sequestration in the spleen, the mechanisms of acquired hemolytic anemia include the factors of increased red cell fragility, destructive agents in the blood serum, and erythrophagocytosis. The overproduction of serum hemolysins unantagonized by antihemolysins results in red cell destruction. Autoagglutinins, autohemolysins and isohemolysins have all been found in the blood serum.

Hyperactivity of the reticuloendothelial system is probably the cause of some cases of hemolytic anemia. The spleen may therefore be only one part of this system causing abnormal red cell destruction. Unless the spleen is of great importance in the individual case, at times a diagnostic problem even to the most astute hematologist, splenectomy will be of little value.

The course of this disease is usually more severe than that of congenital hemolytic anemia. Red cell counts are usually below 2,000,000 and hemolytic crises may cause anemia beyond the regenerative capacity of the bone marrow. Red cell fragility in saline solutions may not be greatly altered. The spleen is usually greatly enlarged. Reticulocytosis is marked and normoblasts may be found in the peripheral blood. Autoagglutinins are often present and the blood serum may contain hemolysins. Reaction to the antihuman globulin test (Coombs') is usually positive.

When the cause of excessive hemolysis cannot be accurately determined, splenectomy is usually considered. At least in part, the anemia in many cases is directly due to splenic hyperactivity. Results of splenectomy cannot always be accurately determined preoperatively. Once the diagnosis is established, adrenocorticotrophic hormone (ACTH) or cortisone should be given a trial of therapy. Failure of response to these drugs initially, or failure of response to an exacerbation after good initial response, warrants splenectomy. Response of acquired hemo-

lytic anemia to splenectomy occurs in only about 50 per cent of the patients, however, in those failing to respond, ACTH or cortisone may be of benefit after splenectomy.

CYSTS

Cysts of the spleen are classified as nonparasitic or parasitic. All are rare. The pathologic and clinical features of various cysts have been reviewed by Fowler, but few other reports occur in the American literature.

Nonparasitic cysts may be divided into primary (true) and secondary (pseudocysts), depending upon whether an epithelial or mesothelial lining exists. They may be of various sizes and either multiple or single. The more common type is the single, subcapsular, secondary cyst, usually resulting from degeneration in an infarct or tumor or the breakdown of a hematoma.

The hydatid cyst is the only parasitic cyst. It occurs in less than 2 per cent of patients with the echinococcus infection.

Symptoms vary with the size and type of cyst. Most of the smaller cysts are asymptomatic, while the larger ones cause abdominal discomfort and are confused with omental, pancreatic or ovarian cysts. Calcification of the cyst wall may simplify the diagnosis. Eosinophilia and a positive reaction to the skin test may differentiate hydatid from nonparasitic cysts.

Treatment consists of splenectomy, if the cyst is centrally located, and marsupialization for drainage, if the cyst is located peripherally and associated with many adhesions. Splenectomy carries a low mortality and is the treatment of choice in most cases. Aspiration, when hydatid cyst is suspected, is dangerous since spillage of cyst contents causes an anaphylactoid reaction.

TUMORS

Tumors of the spleen, both primary and secondary, are even more rare than cysts. All types have been described and include angioma, lymphoma, endothelioma, reticulum cell sarcoma, dermoid epithelial cyst, mesothelial inclusion cysts, fibrosarcoma, fibroma, and leiomyoma. The only important benign tumor is hemangioma and the only important malignant tumor is the sarcoma.

Tumors of the spleen, both primary and secondary, rarely produce symptoms. Nausea, constipation, weight loss and left upper abdominal pain may be noted. The spleen is rarely palpated except when there is a malignant inoperable tumor. Splenectomy is the

treatment of choice and leads to cure for benign tumors, carrying a mortality of about 2 per cent. Since sarcoma is the most common malignant tumor, the operative mortality is higher and the five-year cure rate practically zero.

ANEURYSM OF THE SPLENIC ARTERY

The rare finding of aneurysm of the splenic artery at autopsy is even less often noted clinically, despite the more recent use of contrast arteriography. This aneurysm is the second most common within the abdomen, occurring more often in women than in men. It may be due to arteriosclerosis, trauma or congenital defects, the majority being due to arteriosclerosis. Spontaneous rupture may occur and produce a fatal outcome.

The symptoms vary, but pain, nausea, anorexia, weight loss and occasionally a palpable mass have been noted. These symptoms usually simulate those of chronic pancreatitis, so that diagnosis has been accurately made in less than 10 per cent of the cases. Calcification in the walls of the aneurysm is the only diagnostic radiographic finding, other than that disclosed by the use of aortography.

Treatment consists of excision of the aneurysm if possible, or proximal and distal ligation when excision is considered unsafe. Splenectomy need not necessarily follow ligation of the splenic artery.

INFECTIONS

During recent years, acute infections involving the spleen have been extremely rare, probably owing to widespread use of antibiotics. Chronic infectious processes, primarily or secondarily involving the spleen, are somewhat more common. Abscess of the spleen may develop with infection in an area of hemorrhage or devitalized splenic pulp. During its early stage, the abscess remains within the capsule and may cause no symptoms. With enlargement, perisplenitis may cause pain, chills, fever and splenomegaly, and if drainage is not instituted or splenectomy performed, the possibility of splenic rupture exists, carrying a high mortality. If diagnosis can be made early, splenectomy is the treatment of choice.

Several chronic infections are characterized by splenomegaly. Splenectomy may produce remission of general symptoms, as in Felty's disease, or may be beneficial to the patient in whom secondary hyper-

splenism is associated. The chronic infections with which the spleen may become involved include Felty's syndrome, malaria, tuberculosis and Boeck's sarcoid.

Felty's syndrome is a clinical entity consisting of splenomegaly, anemia and neutropenia, and occurring most often in association with chronic rheumatoid arthritis in women between the ages of forty and sixty years. The pathologic findings in the spleen are not characteristic and the etiologic basis is controversial. The leukopenia may be the result of multiple chronic infections or a splenic hyperfunction of unknown origin. Leukopenia occurs in variable degrees and the arthritis is of several years' duration prior to the onset of the syndrome. The symptoms consist of weakness, frequent episodes of fever, weight loss, swollen and painful joints and multiple skin or oral infections.

Splenectomy has given variable success, but in a number of patients has produced relief not only of the neutropenia and anemia, but also marked improvement in the joint symptoms. Adrenocorticotropin (ACTH) and cortisone may also give temporary and, at times, long-standing symptomatic relief.

The involvement of the spleen in patients with malaria is well known. In certain instances of chronic malaria, the disease may not be diagnosed from peripheral blood smears alone, whereas numerous parasites are harbored within the spleen. No significant diagnostic criteria of malarial infection are present, other than splenomegaly, without other known cause in patients who have been known to have malaria. The only problem presented by the enlarged spleen is the occasional discomfort which it may cause and the susceptibility to either spontaneous or easy traumatic rupture, both of which are direct indications for splenectomy.

As with other portions of the reticuloendothelial system, the spleen may become involved in the chronic systemic disease processes, *tuberculosis* and *Boeck's sarcoid*. The importance of this involvement lies in whether the disease is active and whether it produces hematologic complications. Thrombocytopenia is common but may not necessarily be due to hypersplenism. Other forms of hypersplenism secondary to these chronic disease processes, however, have been reported and the results of splenectomy in the relief of various cytopenias have been quite favorable. The only other indication for surgery in these patients is the occa-

sional markedly enlarged spleen, causing enough abdominal discomfort to warrant its removal.

MISCELLANEOUS DISEASES

Banti's Disease. Portal hypertension is the common denominator of the group of hepatosplenopathies loosely termed Banti's disease. Whether intrahepatic (cirrhosis) or extrahepatic (thrombosis) portal obstruction is present, the splenic changes are similar. The spleen is invariably enlarged. The capsule is thickened and there are usually numerous vascular adhesions. The splenic parenchyma is firm, deep red in color and markedly congested. Fibrosis, with hyperplasia of the reticuloendothelial lining of dilated sinuses, is prominent.

Mediterranean Anemia. This is a familial chronic hemolytic anemia, also called erythroblastic or Cooley's anemia, which occurs usually in children descended from parents of Mediterranean countries. The abnormalities producing anemia consist of a defect in hemoglobin formation and an increased resistance of the red cells to hypotonic saline. Characteristic thickening of the frontal bone, with depression of the nasal bridge, and a mongoloid slant to the eyes help to differentiate this disease. The microcytic anemia may be associated with leukocytosis and is invariably associated with marked hyperplasia of the bone marrow. Splenectomy has been advocated when marked hemolytic activity is present. Most patients will at least maintain a higher red cell count and hemoglobin level and require fewer transfusions following splenectomy.

Storage Diseases. Several diseases due to abnormal lipid metabolism may produce splenomegaly of surgical importance. These include Gaucher's disease, Niemann-Pick disease and Hand-Schüller-Christian disease, in which there is abnormal reticuloendothelial storage respectively of cerebroside, sphingomyelin and cholesterol. Only in Gaucher's disease is splenectomy frequently indicated.

Idiopathic splenomegaly is another term formerly used to denote Gaucher's disease. Patchy pigmentation of the face, conjunctival thickening, hepatomegaly, splenomegaly, flaring of the distal end of the femur, thrombocytopenia and neutropenia may suggest the diagnosis which may be confirmed by the findings of foam cells in the bone marrow. The thrombocytopenia and neutropenia are often due to hyper-

splenism. The diagnosis of Gaucher's disease as the cause of secondary hypersplenism is often not made, however, until the time of splenectomy. Thrombocytopenia and neutropenia may be greatly relieved by splenectomy, but improvement in anemia is only temporary.

THE URINARY SYSTEM

By FRANK HINMAN, JR., M.D.

FRANK HINMAN, JR., is a native Californian who received his college education at Stanford University and his medical education at Johns Hopkins Medical School. He had basic training in general surgery before his graduate training in urologic surgery. He is an Associate Clinical Professor of Urology at the University of California School of Medicine. He has made significant contributions in his experimental studies upon ureteral regeneration.

A picture of an early surgeon operating on the urinary tract (Fig 1) illustrates two things which have made urology a special branch of surgery. One, the urologist uses special instruments and, two, even though he is treating a disease of the lower and middle urinary tracts (in this case removing a stone), he is simultaneously relieving the kidneys of infection and back-pressure. In the field of urology, ultimate or exact diagnosis is usually made by special techniques, for instance, looking into the bladder (cystoscopy) or examining the kidneys with x-rays (pyelography or urography). Diseases of the urinary system are interrelated—what affects one part commonly affects other parts.

A diagram of the urogenital system shows that obstruction at one place along the system causes damage in other parts. As an example, in Figure 2 it is seen that obstruction at the meatus sets up a train of changes: atony, infection and stasis with stone formation and, finally, renal failure. Renal damage alone is not always reversible and may ultimately cause death.

There is a purpose, therefore, in insisting on a reasoned and systematic approach to the diagnosis of urinary diseases.

THE DIAGNOSTIC STEPS IN URINARY TRACT DISEASE MAKING A PRESUMPTIVE UROLOGIC DIAGNOSIS

A physician need not own a cystoscope to examine a patient with urinary complaints and arrive at a satisfactory presumptive diagnosis. Because the parts of the urinary tract are interrelated, deductions are possible from findings at a distance from the seat of the trouble. The tools for making these deductions are common tools and if all are used in every urologic case, few disorders will be overlooked. These tools are:

1. History, with emphasis on urologic features
2. General physical examination
3. Examination of the external genitalia
4. Examination of the urine
5. Rectal examination, and vaginal examination of female
6. Abdominal examination
7. Total renal function tests
8. Roentgenographic study

History. The art of obtaining the urologic history is to elicit all the essential clues so that the subsequent diagnostic steps will be confirmatory rather than exploratory. The complaint is the best lead, especially in

urologic diagnosis, for urologic symptoms are likely to be well localized both in time and in position.

Certain symptoms should be inquired about particularly.

General symptoms. High spiking fever with chills, not chilliness, is characteristic of pyelonephritis. Gastrointestinal symptoms often accompany acute or chronic obstructions of the kidney, since they are supplied by the same nerve tracts. Weight loss increases the seriousness of other complaints.

Pain can give important leads. General areas of reference are the rule: *Renal pain* (Fig. 3A) has a dull aching quality, due to distention of the renal capsule as in pyelonephritis or, less often, in acute obstruction. It is referred to the soft triangle between the lower rib and the vertebral muscles and extends around anteriorly in the area corresponding to the tenth, eleventh and twelfth dermatomes. Pain which is even more localized is suggestive of perirenal involvement.

Acute obstruction to the outflow of the kidney produces renal colic, which is sharp

and severe, but with radiation similar to that produced by capsular distention. Chronic or mild degrees of upper tract obstruction may give only vague gastrointestinal symptoms; these may lead to fruitless investigations of the digestive tract.

Ureteral pain (Fig. 3C) is similar to, but lower than, renal pain. This would be expected because of the lower innervation of the ureter. Low ureteral pain, for example from a stone at the point where the ureter enters the bladder, is referred down the urethra and mimics the pain of prostatitis or posterior urethritis.

Vesical pain (Fig. 3B) arises typically from increased intravesical pressure, as in overdistention of the bladder, or from irritative stimuli within the bladder which in turn produce spasm and thence pain. This pain is usually referred to the suprapubic area. Irritative lesions at the neck of the bladder cause frequent urination and pain referred along the urethra. Prostatic pain may be referred to the suprapubic area and simulate bladder pain.

Prostatic pain (Fig. 3D) is referred prin-

THE URINARY SYSTEM

By FRANK HINMAN, JR., M.D.

FRANK HINMAN, JR., is a native Californian who received his college education at Stanford University and his medical education at Johns Hopkins Medical School. He had basic training in general surgery before his graduate training in urologic surgery. He is an Associate Clinical Professor of Urology at the University of California School of Medicine. He has made significant contributions in his experimental studies upon ureteral regeneration.

A picture of an early surgeon operating on the urinary tract (Fig. 1) illustrates two things which have made urology a special branch of surgery. One, the urologist uses special instruments and, two, even though he is treating a disease of the lower and middle urinary tracts (in this case removing a stone), he is simultaneously relieving the kidneys of infection and back-pressure. In the field of urology, ultimate or exact diagnosis is usually made by special techniques, for instance, looking into the bladder (cystoscopy) or examining the kidneys with x-rays (pyelography or urography). Diseases of the urinary system are interrelated—what affects one part commonly affects other parts.

A diagram of the urogenital system shows that obstruction at one place along the system causes damage in other parts. As an example, in Figure 2 it is seen that obstruction at the meatus sets up a train of changes: atony, infection and stasis with stone formation and, finally, renal failure. Renal damage alone is not always reversible and may ultimately cause death.

There is a purpose, therefore, in insisting on a reasoned and systematic approach to the diagnosis of urinary diseases.

THE DIAGNOSTIC STEPS IN URINARY TRACT DISEASE

MAKING A PRESUMPTIVE UROLOGIC DIAGNOSIS

A physician need not own a cystoscope to examine a patient with urinary complaints and arrive at a satisfactory presumptive diagnosis. Because the parts of the urinary tract are interrelated, deductions are possible from findings at a distance from the seat of the trouble. The tools for making these deductions are common tools and if all are used in every urologic case, few disorders will be overlooked. These tools are:

- 1 History, with emphasis on urologic features
- 2 General physical examination
- 3 Examination of the external genitalia
- 4 Examination of the urine
- 5 Rectal examination, and vaginal examination of female
- 6 Abdominal examination
- 7 Total renal function tests
- 8 Roentgenographic study

History. The art of obtaining the urologic history is to elicit all the essential clues so that the subsequent diagnostic steps will be confirmatory rather than exploratory. The complaint is the best lead, especially in

bleeding is within the urethra, prostate or the vesical neck. Similarly, terminal hematuria indicates lower tract bleeding, since the blood is squeezed out during the peristaltic emptying of the urethra.

Cloudy urine. Causes: phosphate crystals in an alkaline urine, especially in urine after standing, white blood cells, and bacteria. The addition of dilute acid will clear the urine of crystals.

Sterility. Causes: impotency or improper coital technique or timing; infection of accessory sex organs; obstruction to passage of sperm, usually congenital obstruction of vas or epididymis or infectious epididymitis, defective spermatogenesis due to developmental defect in testis, increased scrotal temperature or previous testicular disease.

Impotency. Causes: lack of sexual desire or libido, inability to achieve erection or lack of potency. Accompanying disorders may be premature ejaculation, inability to ejaculate or early subsidence of erection. Few of these disorders arise from organic causes.

The urologic history, then, often gives the first presumptive evidence of the nature and location of disorder in the urinary system.

General Physical Examination. For the urologic patient evaluation of the cardiovascular system should be included. Other areas distant from the genitourinary tract should also be examined. If the patient's history suggests the presence of genitourinary neoplasm, examination of the supraclavicular nodes is in order. The presence of testicular tumor would necessitate examination of the breasts.

Examination of the External Genitalia. A systematic survey of the visible and palpable genitalia is important to the examiner.

The *penis* is inspected, and particular note is made of urethral discharge, meatal anomaly causing stenosis, or ulceration. If any discharge is present, it is expressed and smeared on a slide, and air dried, heat fixed, stained with methylene blue and examined. Mixed organisms and gonococci are looked for particularly.

The *scrotal contents* are palpated by using both hands simultaneously. This allows separation of each testis from its accompanying epididymis in order to distinguish each structure absolutely. Testicular tumors will be within the testis, whereas epididymal enlargement will involve one or both poles of

Figure 3. Referral of genitourinary pain.

Figure 2 Obstruction by stricture at the urethral meatus can result in disease throughout the urinary tract.

cipally to the perineum but may be referred to the low back, the epididymides and down the legs. The source is congestion and inflammation in the prostatic acini and ducts.

Testicular pain (Fig. 3E) is referred to the midabdomen, to the site of the embryologic origin of the gonads. Pain perceived in the testis may arise from the prostate and seminal vesicles, or from the terminal ureter. Renal pain also may be referred to the testis, by the same route along which testicular pain is referred upward.

As can be seen, the referral of urologic pain is not precise, so that it will be more often suggestive than diagnostic.

Other symptoms with special urologic significance are:

Frequency. Causes: (1) excessive fluid intake; (2) small bladder capacity, (3) hyperactive bladder reflexes, of neurogenic origin, which increase motor activity, or irritation in the bladder or posterior urethra, which increases the sensory stimuli.

Urgency. Cause: irritative lesions in blad-

der or prostate, which prematurely stimulate the sensory side of the voiding reflex arc.

Nocturia. Causes: excessive fluid intake; incomplete emptying of bladder so that capacity and increased intravesical pressure lead to more frequent desire to void, mobilization of dependent edema. Other factors are involved which are not understood.

Dysuria. Causes: irritation, especially of the trigone and prostatic urethra by infection, stone or chemicals.

Strangury is very severe dysuria, especially during increasingly frequent passage of smaller and smaller quantities of urine.

Oliguria. Causes are reduced fluid intake, excessive fluid loss (perspiration, vomiting, diarrhea), renal tubular failure, cardiac failure (rarely) and hypotension.

Anuria. Causes of anuria include prolonged hypotension, renal tubular failure and obstruction to the outflow of urine (both ureters or below the neck of the bladder).

Hesitancy. The cause of this condition is inability to relax the bladder neck because of interference by the hypertrophied prostate. Also intravesical pressure must be raised to a greater height before urine is forced past the obstructing prostate gland.

Dribbling. Since resistance to outflow is increased by prostatic hypertrophy, the detrusor muscle continues to contract at the time the stream stops, rather than immediately relaxing as is normally the case when there is no residual urine. This continuing contraction is not strong enough to maintain sizable urinary flow but is enough to force out slowly a few more cubic centimeters of urine.

Incontinence. Causes: (1) stress incontinence from incompetent sphincter muscles, due to relaxation of the pelvic floor or to paralysis or injury, (2) urgency incontinence, which is an extreme form of urinary frequency and urgency, such that the voiding reflex is stimulated so strongly that voluntary control of the sphincter is intermittently lost, (3) overflow incontinence, when the pressure in the overfilled bladder is higher than the resistance of the sphincter, so that intermittent leakage occurs whenever intra-abdominal pressure rises, (4) fistula, and (5) reflex incontinence in the neurogenic bladder, in which filling sets off reflex emptying.

Hematuria. Causes. tumors, stones, infection, tuberculosis, injury. Dark blood suggests upper urinary tract bleeding or residual urine. Initial hematuria with the urine clearing during voiding means that the source of

It is necessary to make trial assumptions:

a. assume 100 cc. residual urine; then the 30' excretion would have to contain 90 per cent of the dye since each 50 cc. contains 30 per cent dye. This would be an abnormally high 30' excretion, so it is impossible for the residual urine to be this great.

b. assume 50 cc. residual urine; then 30' excretion would have to contain 60 per cent of the dye. This is a "high normal" but possible percentage excretion. The higher level of the second, 60', specimen results from the addition of the dye left over from the first voiding.

c. assume no residual urine; but the 30' specimen has to contain more dye than the 60' specimen.

It can be concluded that this patient has less than 100 cc. and more than 0 cc. of residual urine, and probably has a little less than 50 cc.

Roentgenography. A plain film of the abdomen (kidneys, ureter and bladder—KUB) of every patient with symptoms suggestive of disease in the middle or upper tract of the urinary system is obtained.

The film should be read systematically, since it may reveal atrophy of one kidney with compensatory hypertrophy of the other, renal tumor or renal displacement by an adrenal tumor, or metastatic disease, as well as stones in the urinary tract.

Often, greater delineation of the middle and upper urinary tract is necessary. An intravenous urogram (Fig. 7) gives a clearer

outline of the kidney itself and, of course, outlines the drainage system, often clearly and in detail. A postvoiding film allows detection of residual urine, resulting from, for example, prostatic obstruction. Urograms are made before resorting to instrumentation, since they usually make it possible to rule out upper tract abnormalities. If they show abnormalities, retrograde ureteral catheterization and pyelography may be required.

THE PRESUMPTIVE DIAGNOSIS

If the eight steps outlined above are gone through thoughtfully and faithfully for each patient, few diagnostic errors will be made and, in most cases, a presumptive diagnosis which is based on good reasoning will be reached.

For example, a patient is examined with (1) a history of colicky, right-flank pain radiating to the testis; (2) abdominal distention; (3) normal external genitalia; (4) microscopic hematuria with bacteriuria; (5) enlarged prostate, discerned by rectal examination; (6) somewhat distended bladder, judged by percussion; (7) reduced total renal function evaluated by PSP test yielding percentages which indicate the presence of residual urine and (8) a calcific density along the course of the right ureter. These eight steps allow one to arrive simultaneously at two sound presumptive diagnoses: right ureteral calculus and benign prostatic hypertrophy with obstruction. Instrumental steps, which may be both diagnostic and therapeutic, can now be done rationally.

Figure 7. Detail of intravenous urograms compared with a three-dimensional drawing and a coronal section of the same normal kidney. Note cupped calyces on their infundibular stalks and rounded pelvis with funneled ureteropelvic junction.

30'	60 cc	50%
60'	75 cc	15%
Total	135 cc	65%

Admittedly, small errors are inherent in such a method, but they do not exceed 10 per cent and are more than outweighed by the advantages of availability and economy. The results are immediately available to the examiner for correlation with other findings while the patient is still at hand. Finally, it is of value in detecting residual urine, which is important in the urologic evaluation of patients.

Residual urine from incomplete emptying of the bladder cannot be measured directly by the PSP test but can be inferred if normal renal function is assumed. If this assumption cannot be made, the test separates normal renal function and no residual urine from decreased renal function, residual urine or both. This separation is of the utmost importance, for it detects those patients who require further urologic study.

As an example, a normal patient receives a PSP test while he is dehydrated, and again while he is hydrated, usually by drinking two glasses of water at the start of the test.

Dehydrated		
30'	30 cc	50%
60'	30 cc	15%
Total	60 cc	65%

Hydrated		
30'	180 cc	50%
60'	180 cc	15%
Total	360 cc	65%

Note that with normal renal function without residual urine, hydration makes no difference in the excretion of the dye.

Now consider a patient with normal function but with 100 cc. of residual urine in the bladder as a result of incomplete emptying due to prostatic obstruction.

Dehydrated		
30'	30 cc. 11%	The normal 50% PSP was excreted by tubules in 30 cc of urine, but was diluted by 100 cc. residual bladder urine to 130 cc., of which 30 cc was voided 130 cc. 50% 30 cc x x = 11%
60'	30 cc. 12.5%	
		15% PSP was excreted by tubules in 30 cc urine, but was diluted by 100 cc. residual bladder urine which already contained 39% PSP (50% minus 11%) 130 cc.: 39 + 15% 30 cc x x = 12.5%

Figure 6 Curve of PSP excretion from the kidney. Lesser amounts are put out as the blood is cleared of the dye.

Note two things: (1) the total PSP excretion is low, in spite of normal kidney function, and (2) the second specimen contains a little more PSP than the first. Since PSP is put out by the tubules in proportion to the concentration presented to them, the kidneys always excrete more in early periods than in later periods (Fig 6), but if residual urine is present, this relationship will appear to be reversed.

If the same patient is hydrated, has normal renal function but 100 cc. of residual urine:

Hydrated		
30'	180 cc 32%	180 cc renal output containing 50% PSP, diluted by 100 cc. residual bladder urine = 280 cc., then voided 180 cc of this mixture 280 cc.: 50% · 180 cc. x x = 32%
60'	180 cc 21%	180 cc renal output containing 15% PSP, diluted by 100 cc. residual urine containing 18% PSP (50% minus 32%) 280 cc.: 33% · 180 cc x x = 21%
Total	360 cc	53%

A comparison of this last example with the preceding one demonstrates how small urine volumes emphasize the presence of residual urine. During dehydration, the test indicated either poor renal function or residual urine. After hydration, it demonstrated good renal function but did not give information about residual urine. In order to detect residual urine with the PSP test, limit fluids, in order to measure renal function, provide a large fluid intake.

That the PSP test will often give an estimate of the actual volume of residual urine can be shown by an example:

30'	50 cc	30%
-----	-------	-----

Figure 8. Retrograde pyelogram, drawing, overlying cystoscope and ureteral catheters show principal landmarks.

required and the best that medical treatment will assure is arrest, not cure.

Or is it from obstructive renal disease? Then instrumental diagnosis and surgical treatment will locate and remove the obstruction and so allow consequent improvement in renal function (Fig. 9).

INTRINSIC OBSTRUCTIVE

Figure 9. Comparison of medical renal disease, which is not helped by instrumentation or operation, with obstructive renal disease, which is.

Table 1 outlines the conditions causing obstruction.

HYDRONEPHROSIS

The ultimate effect of obstruction anywhere along the urinary tract, from the urethral meatus to the ureteropelvic junction, is hydronephrosis.

When the meatus is partially occluded:

1. The ischiocavernosus muscle does not empty the urethra completely, so dilatation and even saclike outpouchings appear.

2. The detrusor muscle of the bladder first contracts with more vigor to push past the obstruction and hypertrophies. The muscle bundles thicken, the submucosa between weakens and gives way, forming diverticula.

When this compensatory process can no longer balance the obstruction, decompensation occurs. The detrusor muscle is no longer able to empty the bladder completely and urine remains after voiding.

Finally, if the obstruction is not relieved, the muscle, being overstretched, loses its contractibility and atony results.

3. The ureteral pressure increases, since each peristaltic effort must force urine past the thickened bladder wall so that the ureter, too, goes through the stages of hypertrophy, decompensation and atony (Fig. 10). The lower ureter decompensates first, leaving the upper ureter unprotected. The decompensated portions gradually extend upward, until the renal pelvis and finally the calices are dilated, and residual urine remains in

CONFIRMING A PRESUMPTIVE DIAGNOSIS

Catheterization. The ability to pass a catheter through the urethra indicates that there are no urethral strictures. Catheterization also confirms the presence and permits measurement of the amount of residual urine if the PSP test gave equivocal results. It is not used to secure a sterile urine specimen from the male but may be so used in the female. Catheterization also precedes cystography, which is filming of the bladder filled with a contrast medium, and is necessary for cystometrography.

The rationale for completing noninstrumental steps before introducing catheters or other instruments can be made obvious by one example. A patient with symptoms suggestive of urethritis or prostatitis is catheterized, in order to determine whether residual urine is present, immediately after his urologic history is taken. The catheter irritates the urethra, so that when the first glass of urine is collected, it contains red blood cells and massage of the prostate produces more blood cells. The chance has been lost for knowing if an underlying urethritis is present.

Catheterization in the male is done by cleansing the meatus, introducing a liquid or jelly anesthetic agent without pressure, waiting five minutes, gently introducing 5 or 10 cc of lubricating jelly from a tube or syringe and then slowly inserting the catheter. Often the passage of the catheter is obstructed at the external urethral sphincter, gentle persistent pressure applied by the examiner allows it to proceed; each time the patient relaxes the reflexly contracted sphincter. It is good practice to prescribe an antispasmodic and a sulfonamide for twenty-four hours following any instrumentation in order to reduce irritation and to decrease the chance of provoking infection.

Urethral Exploration. If the catheter does not pass through the urethra, fine woven filiforms, to which larger metal followers are attached, may be introduced to determine the site and extent of the obstruction and to overcome it. Metal sounds are used for the same purpose in cases of strictures of larger caliber.

Panendoscopy, the visualization of the urethra with an instrument containing a lens and light, adds to our knowledge of the lesion in the urethra. Filling the urethra from the meatus with opaque jelly allows x-ray visualization which is especially valuable for detecting abnormalities in the posterior urethra.

Exploration of the Bladder. A cystoscope permits excellent views of the entire bladder wall, including the trigone and vesical neck. It is for this reason that cytologic study of bladder urine for tumor cells has not been very widely used. It is too easy to examine the bladder wall directly.

Upper Urinary Tract Studies. In most cases, intravenous urograms give adequate and physiologic information about the upper urinary tract. However, if detail is lacking, if renal function is depressed or if infection must be traced to its source, retrograde ureteral catheterization is necessary.

Small catheters are passed via the cystoscope through the ureteral orifices and into the renal pelves in order to collect specimens of urine from the separate pelves. These specimens are utilized for microscopic examination, culture preparation and for differential function tests. They also allow retrograde injection of opaque media to produce x-ray pictures of great contrast of the renal pelves, calices and ureters (Fig. 8).

Other studies are used for dealing with special problems. Presacral pneumograms outline the renal and adrenal areas with oxygen and produce sharp contrast on the x-ray film. Aortography demonstrates the renal arteries and vascular bed of the kidneys and is of special value in diagnosing vascular obstructions in hypertensive patients. Antegrade pyelography, accomplished by inserting a needle directly into the dilated renal pelvis and injecting dye, can be used when retrograde filling is not possible. Cineradiography, using an image amplifier, demonstrates dysfunction of peristalsis and of micturition.

Reaching the correct diagnosis in urology is not so much a matter of sagacity as it is of careful and systematic observation and use of precise techniques which lead inductively to the correct conclusion.

OBSTRUCTION OF THE URINARY TRACT

Obstruction is the watchword of urologists. Not only can it destroy the kidneys by back-pressure alone, but it can indirectly damage the renal parenchyma by fostering infection and encouraging the formation of stones.

When poor renal function is detected by an impaired PSP excretion or, later, by an increase in the serum nonprotein nitrogen level, the physician asks himself:

Is it due to intrinsic renal disease (Fig. 9)? In this case active intervention is not

all parts of the urinary tract. Renal secretory pressure now is the only force remaining to push past the obstruction.

4. The renal tubules dilate, but, more important, the arteries between the cortex and medulla are stretched and constricted by the pelviocaliceal distention of the pelvis and calices. This results in partial ischemia, which speeds the destruction of the tubules and glomeruli.

Secondary effects of obstruction are often as damaging as the obstruction itself (Fig. 11). The presence of residual urine allows a single contaminating bacterium to multiply before it is flushed from the urinary system, so that infection follows obstruction in the majority of cases. It is axiomatic that pyuria is due to obstruction until proved otherwise and bacilluria accompanied by relatively few white blood cells is virtually always good evidence for stagnation. Calculous formation occurs more readily after obstruction too. The nidus which would normally be passed is retained and is augmented by further precipitation in the presence of alkaline infection.

RENAL ADJUSTMENTS TO OBSTRUCTION

Backflow (Fig. 12) from the renal pelvis and calices into the tubules, veins and lymphatics probably begins as a safety mechanism during minor degrees of obstruction or diuresis. With more complete blockage, backflow carries back into the circulation only a small portion of the secreted urine. However, these routes make possible a slow circulation of urine and prevent the simple atrophy that would occur should the urine have no egress.

Compensatory hypertrophy of the other

kidney begins as soon as one kidney is obstructed, apparently in response to the doubled load of waste products circulating to it. After one kidney has been obstructed for two weeks, the normal kidney has the functional power that both kidneys originally had.

DIAGNOSIS

The diagnosis of obstruction is made on the presumptive findings plus the instrumental findings. It can rarely be made from the history and symptomatology alone. In the final analysis, the pyelogram will give the most information concerning the degree of obstruction, degree of damage and the site of obstruction if it is in the upper tract. An x-ray film made ten or fifteen minutes after injection of the dye into the renal pelvis through a ureteral catheter will often give valuable information as to the site and degree of obstruction by showing the retention of dye after this interval. The normal kidney will empty itself in this period.

Two factors are of great importance in the study of a patient with hydronephrosis: the estimation of individual renal function and determination of the site of the obstruction. An estimation of the relative function of the two kidneys assesses the degree of damage to the hydronephrotic kidney to determine whether it is worth preserving and ascertains that the contralateral kidney is capable of supporting life in case of removal of the damaged kidney. If the damaged kidney is not capable of supporting life alone, it should be removed. Consideration of the effects of renal counterbalance will enter into the decision as to the proper treatment of hydronephrosis since repair of a very

Fig. 12. Obstruction distally causes urine to flow back up the tubules or into the veins or lymphatics at the fornices.

CHAPTER 25. THE URINARY SYSTEM

Table 1. Conditions Causing Obstruction

Table 1. Conditions Causing Obstruction		
ANATOMIC LOCATION	CONGENITAL TYPES	ACQUIRED TYPES
Lower tract Urethral	Congenital phimosis Atresia Stricture (meatus) Diverticulum Abnormal openings and anomalies	Acquired phimosis Stricture Stone Tumor Diverticulum Fistula
Urethrovaginal	Posterior urethral valves Hypertrophied verumontanum Contracture of the neck Hypertrophy of the neck	Prostatism Hyperplasia Cancer Contracture or median bar Cysts Essential sphincter spasm
Vesical	Anomalies Congenital diverticulum	Tumor Stone Diverticulum Hypertrophy of interureteric ridge Neurogenic bladder

Pelvic and renal	Ureteropelvic junction obstruction Anomalous vessels High insertion	Ureteropelvic conditions Pelvic and caliceal Stone Tumor Prosis Stricture

Figure 10. The consequences of distal obstruction are, first, compensatory hypertrophy of the smooth muscle to overcome the obstruction, second, muscular decompensation and inability to expel the contents completely (residual urine), and, finally, irreversible atony.

Figure 11. Obstruction not only damages the kidney directly by back-pressure, but also fosters infection and stones, which in turn injure the kidney.

can be reached by palpation. Is the infection "simple"?

Mixed infection. Are the external genitalia free of vulvitis or vaginitis? Is the total renal function normal? Decreased PSP excretion means residual urine, bilateral renal damage, or both, and requires detailed instrumental study. Are abnormalities detected by intravenous urography, especially upper tract anomalies and residual urine?

If any of these diagnostic steps indicates the presence of a disease process or a structural abnormality, instrumental steps are in order, catheterization both for culture preparation and to detect residual urine; cystometrography to determine the presence of any abnormality of bladder function; cystography to detect any incompetency of the ureterovesical valves or abnormalities of the vesical neck. Instillation of 5 cc. of light Lipiodol into the bladder will demonstrate residual urine when the child cannot void on command. Since Lipiodol floats, it will still be seen in an x-ray film obtained two days later

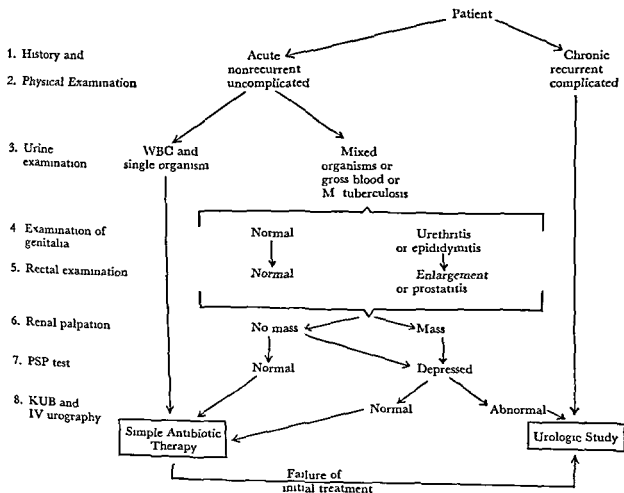

if the child has not completely emptied his bladder during that time.

If upper urinary tract abnormalities are seen in the intravenous urograms, small catheters can be passed to the kidneys and specimens obtained for differential culture preparations and PSP tests, and pyelograms, which show greater detail than that present in intravenous urograms, can be made by injection of a concentrated radiopaque solution into the renal pelvis.

These instrumental steps lay bare the anatomic and physiologic details of the entire urinary tract and serve as the basis for specific therapy.

Treatment may be correction of the vesical neck obstruction by repeated, increased dilatation of the urethra or by a plastic operation on the vesical neck; correction of the incompetency of the ureterovesical valves, which become incompetent from long-standing obstruction at the bladder neck, or correction of the obstruction at the junction of the renal pelvis with the ureter, a common site for congenital abnormality.

Table 2.

poor kidney is useless if the normal kidney has taken over the whole excretory load. The damaged kidney will not be stimulated to regain its function.

The second factor of importance is the location of the site of the obstruction. Determination of exactly what pathologic process has resulted in the obstruction is of the greatest importance. Examples would be benign prostatic hypertrophy in the urethra, neurogenic bladder, tumor or stone in the ureter, and at the ureteropelvic junction, aberrant vessel or congenital stricture. If the hydronephrotic kidney is to be preserved, the attack must be leveled at the site of the obstructive lesion.

TREATMENT

The treatment of hydronephrosis resulting from supravescical obstruction is more complicated than that arising from prostatic enlargement since the delicate technical procedures on the ureter, ureteropelvic junction and renal pelvis are fraught with hazards of judgment and of technique. The principal factors affecting surgical treatment of obstruction of the upper urinary tract with hydronephrosis are as follows.

1. If the patient is young, all portions of the renal tissue should be conserved since injuries or disease later in life may damage the remaining kidney. Older people, on the other hand, do not need this insurance and would be more greatly harmed by a later nephrectomy should the conservative operation fail.

2. If the contralateral kidney is somewhat damaged or is involved in a process which could be progressive, then a greater effort must be made to save the ipsilateral kidney. On the other hand, if the other kidney is quite normal and the hydronephrotic kidney is greatly damaged, one can expect little recovery in the hydronephrotic kidney after the repair, since the factors of renal counterbalance will come into play. Then nephrectomy is often the wiser choice.

3. If there is severe infection in the hydronephrotic kidney which has involved the parenchymal tissue, there is less chance of this kidney returning to relatively normal function. This would be a factor in advocating nephrectomy rather than repair.

However, in actual practice the treatment decided upon for unilateral or bilateral hydronephrosis will in the last analysis be reached in assessing the many factors involved and weighing them against exper-

ience with the kind of surgical repair required.

Obstruction is the cause of irreversible renal insufficiency and eventual death. Obstruction is the result of some other, usually correctable, disease of the urinary tract. It fosters secondary disorders, such as infection and the formation of stones. Finally, presence of obstruction can be detected by urologic tests and instrumentation and can be corrected surgically by the application of urologic principles.

INFECTION

When confronted with infection anywhere in the urinary tract, it should be remembered that its parts are connected by a column of fluid, by a continuous transitional cell lining and by lymphatic channels. Bacteria in one area can therefore spread to adjacent areas through the urine, along the surfaces of the urethra and prostate or through lymphatic drainage from the bladder to the kidneys.

Stasis of urine from any obstruction to its outflow greatly enhances the spread of bacteria in the urine and perpetuates the resulting infection. Foreign bodies also keep infection active.

ACUTE PYELONEPHRITIS

Sudden infection of one or both kidneys may occur in either sex and in any age group, but it is rare in men without some specific underlying disease such as prostatitis, prostatic obstruction with residual urine or calculi.

In children, especially little girls, acute pyelonephritis is rather frequently seen. Without prodromata, or following a mild infection of the upper respiratory tract, a high fever and frequency or burning of urination will appear. Sometimes no symptoms are apparent and the diagnosis is made by examination of the urine. The short female urethra probably allows bacteria to ascend easily from the vulva to the bladder. However, more than accessibility is required for contaminating bacteria to multiply in sufficient numbers to constitute infection. The necessary additional factor is some abnormality of structure or function of the bladder and bladder neck or, less often, of the upper urinary tract.

Steps must be taken to detect these abnormalities in any child who has a second bout of pyelonephritis (Table 2). Is the infection in one kidney or both? A decision

ally this can be accomplished without the necessity of interrupting the pregnancy. The therapeutic intent is to maintain the patient with a minimum of symptoms, making no heroic attempt to clear the infection entirely. Thus, the patient may go through pregnancy to begin intensive treatment more safely and effectively in the puerperium. If the infection is associated with stone or actual ureteral obstruction, an attempt is made to assist the patient through her pregnancy before a surgical procedure is proposed.

TUBERCULOSIS OF THE URINARY TRACT

From a pulmonary lesion, the tubercle bacilli are disseminated by the blood stream and lodge in the renal cortex. Most of them are eliminated by the tissue defense mechanism, but occasionally a clump will establish itself. A tubercle forms which grows and throws off red and white blood cells and bacilli. Although the bacterial spread is initially bilateral, often it actually causes disease in only one kidney.

The first sign the patient notices may be gross total hematuria. As the disease progresses, the ureters and bladder become infected, giving symptoms of cystitis and often extreme burning and urgency. More bleeding may occur. Eventually, scarring of the vesical wall produces a bladder of very small capacity.

Carned from the kidney by the urine, the tubercle bacilli lodge in the posterior urethra and spread to the seminal vesicles, prostate and, by the ejaculatory ducts, to the epididymides. Such involvement usually provokes few symptoms.

The diagnosis of genitourinary tuberculosis is made on the basis of a past history of exposure to and of pulmonary involvement by tuberculosis. Upon examination of the external genitalia, a thick, hard epididymis with beading of the vas deferens may be noted. A methylene blue smear made from a urine specimen contains pus cells without organisms. Stains for acid-fast bacteria will be positive in over half the cases. Pyuria without bacilluria means tuberculosis until proved otherwise. Large overnight specimens are obtained for concentration in the laboratory for smear, culture and guinea

may al-
seminal

function is usually normal unless the disease is bilateral and advanced. A plain film of the abdomen often will allow visualization of renal parenchymal calcification, typical of

the slow necrotic reaction of the tissues to the bacilli.

Instrumental study aims at localizing the disease. Retrograde ureteral catheterization is performed to determine whether the infection is in one or both kidneys and whether renal damage is greater on one side.

Treatment is primarily medical. Triple-drug therapy is prescribed for the patient: streptomycin, 1 gm. twice weekly; para-aminohippuric acid, 5 gm. three times a day; and isoniazid, 100 mg. three times a day. If one kidney is greatly destroyed and the other normal, nephrectomy may be done after one to three months of medical treatment. The trend, however, is toward dependence on long-term drug therapy alone, controlled by making new cultures semi-annually. The treatment is tentatively stopped after two negative cultures are obtained, but new cultures are made to be sure reactivation has not occurred. Bed rest is also important for the patient.

Infection of the urinary tract almost always means impaired drainage. If the infection is not cleared readily, the reason must be found by detailed urologic study. The real purpose is to find the obstruction or foreign body which is keeping the infection active and then to remove the cause.

ANOMALIES OF THE KIDNEY, URETER AND BLADDER

ANOMALIES OF THE KIDNEY AND URETER

The ureter is formed embryologically as a bud from the wolffian duct and grows up retroperitoneally to touch the metanephrogenic tissue, where it branches to form the calices and collecting tubules of the kidney, joining the distal convoluted tubules. It is easy to see that developmental arrest occurring while these complicated connections are being formed would result in anomalies. For example, agenesis results if no bud forms (Fig. 13A). If two buds form on one side, or one bud branches, a double kidney results, composed of two ureteral and pelvicaliceal systems (Fig. 13B).

Fusion of the embryonic tissue, if at the lower pole, produces a horseshoe kidney (Fig. 13C). Drainage in the case of this anomaly is often poor and obstruction and infection result.

Improper connection of the collecting tubules to the distal convoluted tubules results in congenital polycystic kidneys in which the greater portion of the parenchyma is replaced by cysts. Polycystic disease is

Other urinary abnormalities must be looked for since the urinary tract is the most common site of congenital anomalies.

Only when the anatomic and resulting functional disturbances which permitted the infection to become established have been corrected should an attempt be made to eradicate the infection. Otherwise, recurrence and progression are inevitable and good antibiotics will be wasted because of the emergence of a resistant flora.

In adult women, acute pyelonephritis similarly arises from urethral sources but is less often associated with bladder and renal abnormalities. One attack may be treated with a sulfonamide only. However, if the infection is not cleared or if it recurs, investigation is needed. The schema shows when complete investigation, including retrograde urologic study, is required (Table 2)

Most often, episodes of acute infection of the kidney are interspersed with recurrent bouts of cystitis. Cystoscopy will reveal reduction of the caliber of the urethra. Appropriate treatment consists of urethral dilations, then antibiotic therapy, with vaginal estrogen suppositories if indicated.

In adult men, acute pyelonephritis arises most commonly from infection of the prostate associated with some prostatic obstruction. The residual urine gives the bacteria a chance to multiply and ascend to the kidneys. A three-glass test will show shreds arising from infected prostatic ducts in the first glass and subsequent massage will produce pus. Intravenous urograms are needed to rule out the upper tract as the source of the infection.

Antibacterial therapy will usually clear the initial attack promptly, but treatment directed at the prostate may be necessary for permanent control.

CHRONIC PYELONEPHRITIS

This is an entity to be contrasted to chronic renal infection secondary to obstruction or stone. It occurs most commonly in middle-aged women and ultimately destroys the kidneys. Hypertension may occur from renal ischemia. If the disease is unilateral, hypertension may be reversed by nephrectomy. The pathologic changes may occur either unilaterally or bilaterally. Characteristically, the process is distributed in patches throughout the kidney. Many different pathologic changes may be going on at the same time. For instance, focal abscesses, patchy interstitial inflammation with or without scarring and fibrosis, tubular atrophy as

well as tubular dilation and some destruction of glomeruli may all be found in the same kidney. In late stages there is a great amount of diffuse scarring which constricts the infundibula in particular and an x-ray picture characteristically shows a small kidney with long, narrow, spider-like infundibular channels joining the calices to the renal pelvis. In addition, changes occur secondary to the parenchymal inflammation in the epithelium of the pelvis and ureter. Such changes are pyelitis cystica, in which small cysts dot the surface, pyelitis granulosa and emphysematosa. There may be metaplasia or leukoplakia and often there is dilation and scarring of the structures. Of particular importance is the fact that the scarring and other changes occurring with pyelonephritis provide impregnable positions for the lodging of bacteria so that the process is self-perpetuating.

The diagnosis is made after examination of the urine of a patient who may or may not have had acute attacks of pyelonephritis. Total renal function will be diminished. Intravenous urograms will show reduction in renal mass, with spidery calices but no obstructive dilatation. A lower tract source must be eliminated and intensive prolonged antibiotic therapy administered. Recurrence is the rule, since only suppression is achieved. The same organism in the same concentration is found in cultures when the drug is stopped.

RENAL INFECTION DURING PREGNANCY

Renal infection during pregnancy occurs in approximately one out of every twelve pregnant women. Etiologically, since the colon bacillus or one of the colon bacillus group is found in over 80 per cent of the cases, it is probable that the intestinal tract is the common source of the infection. The secondary factors which allow the infection to lodge and progress are two: (1) Stasis produced by the obstruction of the lower ureter—most often the right ureter—by the fetus. However, infection often occurs early in the course of pregnancy before the uterus has grown large enough to be the cause of such obstruction. (2) Probably of more importance is a hormonal factor which causes lowered ureteral tone and consequent dilation. Dilation of the ureter occurs in from 80 to 90 per cent of all pregnant women, although, of course, infection does not invariably accompany it. The diagnosis and treatment in these patients are similar to those in ordinary acute py-

ally this can be accomplished without the necessity of interrupting the pregnancy. The therapeutic intent is to maintain the patient with a minimum of symptoms, making no heroic attempt to clear the infection entirely. Thus, the patient may go through pregnancy to begin intensive treatment more safely and effectively in the puerperium. If the infection is associated with stone or actual ureteral obstruction, an attempt is made to assist the patient through her pregnancy before a surgical procedure is proposed.

TUBERCULOSIS OF THE URINARY TRACT

From a pulmonary lesion, the tubercle bacilli are disseminated by the blood stream and lodge in the renal cortex. Most of them are eliminated by the tissue defense mechanism, but occasionally a clump will establish itself. A tubercle forms which grows and throws off red and white blood cells and bacilli. Although the bacterial spread is initially bilateral, often it actually causes disease in only one kidney.

The first sign the patient notices may be gross total hematuria. As the disease progresses, the ureters and bladder become infected, giving symptoms of cystitis and often extreme burning and urgency. More bleeding may occur. Eventually, scarring of the vesical wall produces a bladder of very small capacity.

Carried from the kidney by the urine, the tubercle bacilli lodge in the posterior urethra and spread to the seminal vesicles, prostate and, by the ejaculatory ducts, to the epididymides. Such involvement usually provokes few symptoms.

The diagnosis of genitourinary tuberculosis is made on the basis of a past history of exposure to and of pulmonary involvement by tuberculosis. Upon examination of the external genitalia, a thick, hard epididymis with beading of the vas deferens may be noted. A methylene blue smear made from a urine specimen contains pus cells without organisms. Stains for acid-fast bacteria will be positive in over half the cases. Pyuria without bacilluria means tuberculosis until proved otherwise. Large overnight specimens are obtained for concentration in the laboratory for smear, culture and guinea pig inoculation. Rectal examination may allow a nodular prostate or thick firm seminal vesicles to be discerned. Total renal function is usually normal unless the disease is bilateral and advanced. A plain film of the abdomen often will allow visualization of renal parenchymal calcification, typical of

the slow necrotic reaction of the tissues to the bacilli.

Instrumental study aims at localizing the disease. Retrograde ureteral catheterization is performed to determine whether the infection is in one or both kidneys and whether renal damage is greater on one side.

Treatment is primarily medical. Triple-drug therapy is prescribed for the patient: streptomycin, 1 gm. twice weekly; para-aminohippuric acid, 5 gm. three times a day; and isoniazid, 100 mg. three times a day. The trend, however, is toward dependence on long-term drug therapy alone, controlled by making new cultures semi-annually. The treatment is tentatively stopped after two negative cultures are obtained, but new cultures are made to be sure reactivation has not occurred. Bed rest is also important for the patient.

Infection of the urinary tract almost always means impaired drainage. If the infection is not cleared readily, the reason must be found by detailed urologic study. The real purpose is to find the obstruction or foreign body which is keeping the infection active and then to remove the cause.

ANOMALIES OF THE KIDNEY, URETER AND BLADDER

ANOMALIES OF THE KIDNEY AND URETER

The ureter is formed embryologically as a bud from the wolffian duct and grows up retroperitoneally to touch the metanephrogenic tissue, where it branches to form the calices and collecting tubules of the kidney, joining the distal convoluted tubules. It is easy to see that developmental arrest occurring while these complicated connections are being formed would result in anomalies. For example, agenesis results if no bud forms (Fig. 13A). If two buds form on one side, or one bud branches, a double kidney results, composed of two ureteral and pelvicaliceal systems (Fig. 13B).

Fusion of the embryonic tissue, if at the lower pole, produces a horseshoe kidney (Fig. 13C). Drainage in the case of this anomaly is often poor and obstruction and infection result.

Improper connection of the collecting tubules to the distal convoluted tubules results in congenital polycystic kidneys in which the greater portion of the parenchyma is replaced by cysts. Polycystic disease is

Figure 13. A, Renal agenesis B, Renal and ureteral duplication C, Horseshoe kidney D Retrocaval ureter. E, Ureterocele

hereditary. It is seen either in infants in whom bilateral masses are felt at, or soon after, birth and in whom the disease is usually fatal well before adolescence, or in adults over the age of thirty. In adults, pain, hematuria or infection may lead to the diagnosis or the first external evidence may be the symptoms of renal insufficiency, often with hypertension. Pyelography allows the typical elongated and curved calices to be seen. Treatment is usually medical.

With developmental anomaly of the vena cava, the right ureter may remain behind and medial to it, resulting in a retrocaval ureter (Fig. 13D). It is then more liable to obstruction. Treatment is division and reanastomosis of either the ureter or the vena cava.

If the ureteral bud forms improperly at its junction with the bladder, stenosis remains, which forces dilatation and prolapse of the ureteral wall into the bladder forming a ureterocele (Fig. 13E). The result is upper tract obstruction. A filling defect in the bladder can be seen on the intravenous urograms; cystoscopically the cystlike structure can be identified. Cure is effected by incising the stenotic orifice and wall of the ureterocele.

ANOMALIES OF THE BLADDER

Exstrophy of the bladder is the most common major anomaly. Development of the anterior wall of the bladder and urethra, as well as of the overlying abdominal wall, is incomplete, so that these organs lie open on the abdomen. If only the urethra fails to close, epispadias results.

Treatment ideally should provide a functional urinary reservoir. Restoration of the bladder to the abdomen has not been very successful because its wall is abnormal and because it possesses no effective urethral sphincter. Diversion of the urine to the rectum retains a reservoir but encourages infection, while diversion to the skin via an ileal conduit reduces the chance of renal infection but does not provide urinary continence.

Should obliteration of the allantois fail, a fistulous connection persists between the dome of the bladder and the umbilicus. During voiding, a fine stream of urine issues from the umbilicus. If both ends of the allantois become closed, a urachal cyst results, forming a midline subfascial mass which may periodically burst into the bladder or drain out through the umbilicus.

Anomalous development is a common source of obstruction in the urinary tract, whether the abnormality is in the kidney, ureter, bladder or urethra. Early detection is important so that the defect can be corrected before the appearance of irreversible changes.

INJURIES TO THE KIDNEY, URETER AND BLADDER

RENAL INJURIES

Direct blows to the kidney can cause (Fig. 14): contusion without distortion of the renal outline or of the collecting system (A), external rupture, through the capsule, with severe retroperitoneal bleeding and obliteration of the renal outline and psoas shadow (B); internal rupture, tearing into a calyx, with bleeding and pyelographic distortion (C); and combined rupture through the pelvis and capsule (D).

Symptoms range from slight flank tenderness with hematuria, detectable only microscopically, to severe pain in the flank, a mass in the retroperitoneal area and gross bleeding. If the bleeding into the retroperitoneal space is profuse, shock supervenes.

Diagnosis of renal injury is aided by intravenous pyelography. Slight damage is present if the kidney f

Figure 14. Renal injuries.

in whole or in part. Retrograde pycelography may be needed to define the damaged area so that primary surgical repair can be performed.

Treatment is usually nonsurgical unless the bleeding continues or, more rarely, infection occurs. If the mass in the flank grows progressively larger, if the shock is not readily corrected by blood transfusions or if the kidney is shown by pycelography to be greatly deranged, operation is necessary either to repair the lacerations and control the bleeding or, more often, to remove the kidney.

URETERAL INJURIES

The ureter, because of its size and its movable position in the retroperitoneal fat, is rarely injured by external violence but is occasionally damaged during gynecologic operations in the pelvic area or, less often, during instrumental attempts to remove stones.

VESICAL INJURIES

The bladder must be distended to be injured by a direct blow. It may be perforated by neighboring bony structures.

The most constant symptom or sign is hematuria. In severe injuries the patient has marked pain over the area and abdominal rigidity if the rupture extends intraperitoneally. Often he is unable to pass urine at all. Shock is frequently present.

The diagnosis is best made by cystogram, so that the site and extent of the extravasation can be actually seen on the x-ray film. The recovery of a measured amount of water instilled through a catheter is less reliable assurance that rupture has not occurred. In-

travenous urography is a safe method to show the presence of extravasation.

The treatment is drainage of the bladder suprapubically with closure of the laceration if it is intraperitoneal or if it is large.

Injuries of the urinary tract are dangerous because of the frequently severe hemorrhage and especially because of the extravasation of urine with its malign consequences. Restoration of continuity of the urinary passages and adequate drainage of areas of leakage are the prime purposes of treatment.

CALCULOUS DISEASE

THE CAUSES OF STONE FORMATION

Two factors must be present for a stone to develop: (1) a nidus to serve as a center for the precipitation of calcareous materials and (2) an imbalance between the amount and type of crystalloid substance held in the urine and the concentration and type of colloid substances which hold the crystalloids in solution (Table 3).

The Nidus. Because of its surface activity, a nidus provides a nucleus for the precipitation of the components of stone. By spectrophotometry, the chemist can not only analyze the bulk of the stone, but he can also determine the composition of the original core. Then the physician knows the original metabolic factor which initiated the formation of the stone.

There are four sources for a nidus:

1. *Subepithelial injury.* By careful study of hundreds of sections of kidneys obtained at postmortem examination, Randall found calcified plaques resulting from local tissue

Table 3. Factors in Renal Calculi Formation

injury in the renal papillae of almost one-fourth of them. In 8 per cent he found actual stones adherent to the papillae. Similar changes have been observed beneath the epithelium of the renal collecting tubules. Somewhat analogous have been the findings of Carr that calcifications occur in the lymphatics draining the calices, which may grow and break through into direct contact with the caliceal urine.

2. *Epithelial changes to which colloids adhere* Stones can be made to form in rats maintained on a diet deficient in vitamin A. Such a deficiency would be rare in the human and these experiments merely illustrate that epithelial changes themselves are enough to initiate stone formation. Infection and surgical injury are much more common as clinical causes for such alteration of the epithelium of the renal pelvis.

3. *Formation of micelles* A micelle is an aggregate of crystalloids which reaches colloidal size, it then can act as a colloid to bind further crystalloids. A micelle can be thought of as an embryonic stone.

4. *Foreign body.* This is the obvious nidus: a residual stone, nonabsorbable suture, retention catheter and the like.

Colloid-Crystalloid Imbalance. More than a nidus is necessary for stone formation. The salts must be precipitated in an organic matrix for a calculus to grow. Ordinarily, the urine is supersaturated with crystalloids, which are held in solution by colloidal substances. This balance may be upset by the urine's providing too many crystalloids, by its having too few protective, hydrophilic colloids or by its having a preponderance of nonprotective, hydrophobic colloids.

Concentration of Solutes. Obviously water is a major factor since, generally, the more dilute the solutes, the less likely are aggregation and concretion to take place. Overhydration is good basic treatment for the patient who recurrently forms stones.

Increased calcium excretion in the urine can be detected by adding Sulkowitch reagent, which precipitates the calcium as the

insoluble oxalate. This test should be made on the concentrated urine specimen of all patients with stones, since 5 per cent of them have hyperparathyroidism. Hyperactivity of the parathyroid glands causes an increase in serum calcium and a decrease in serum phosphorus together with a rise in the urinary excretion of both substances. Hyperparathyroidism should be suspected in any patient with opaque stones, especially if he also has excessive calcium in the urine. Proof of the diagnosis rests, however, on finding an elevated serum calcium level by a reliable laboratory. The treatment is removal of the parathyroid adenoma.

Since the bones form so large a portion of the body, any factors which cause skeletal breakdown will produce hypercalciuria. An outstanding factor is prolonged immobilization. Resorption of bone begins upon removal of weight bearing. The result is an outpouring of calcium and phosphorus for eight or nine weeks until equilibrium of bone stress is restored. Not only is there increased calcium available for stone formation, but renal drainage is impaired and small nidi are retained. The administration of calcium to such a patient in an attempt to reverse the osteomalacia would only increase the level of calcium in the urine.

Renal tubular acidosis, while not common, is an interesting example of hypercalciuria. It occurs because the tubules cannot form ammonia and so calcium and potassium are used to neutralize the acid. The excessive calcium excretion causes nephrocalcinosis or renal calculi, as well as producing osteomalacia. These derangements can be corrected by the oral administration of enough sodium bicarbonate to provide sodium ions to substitute for the ammonium ion.

Other substances besides calcium can be excreted in excessive amounts. In individuals suffering from a familial disorder of excessive amino acid excretion, cystine competes unsuccessfully with lysine in the defective tubular resorption mechanism and is excreted in excessive amounts, forming stones.

Since cystine is soluble in alkaline urine, recurrence can be reduced by alkalization.

Uric acid, excreted in excess by patients with gout, may pass as crystals to produce colic, may form the nidus for calcium stones or may gather into aggregates as a true stone. Larger amounts of uric acid are also excreted in patients with leukemia, especially after cortisone therapy.

Colloid effects. The urine must be thought of as an extension of the extracellular ground substance. The colloids in the urine are mucopolysaccharides. An example is hyaluronic acid, normally disposed in the extracellular cement. These colloids are either protective or stone forming. The protectiveness of the colloid depends on its quantity and its molecular weight. By absorption on the hydrophobic stone-forming colloid, the hydrophilic colloid exerts its protective action. The protective colloid apparently, before agglomeration, acts to prevent crystal orientation and growth.

The hydrophobic, stone-forming colloids, on the other hand, compose the organic matrix of the stone. They are present in "stone formers" in three to eleven times the normal quantity. Because of different electrophoretic characteristics from the hydrophilic colloids, they absorb on a nucleus and initiate a stone. Several micelles plus these colloids yield a nucleus.

Stasis. Obstruction to the urinary outflow has two effects. One is retention of the nidus (Fig. 15) or embryonic stone, and the other is the promotion of infection, which in turn enhances the deposition of calcific substances.

Infection. Urea-splitting organisms decrease the solubility of calcium phosphate by altering the pH of the normally acid urine. For example, if normal urine at pH 5.6 is just saturated with calcium phosphate, it will be saturated two times at pH 6 and eight times at pH 7.

In addition, infection alters the composition of the colloids in the urine and the altered colloids from the damaged lining help make up the matrix of the stone.

Etiologic Study. First, hyperparathyroidism must be ruled out by means of a Sulzowitch test and by serum calcium and phosphorus determinations in a reliable laboratory.

Second, the urine must be tested for cystine with the nitroprusside test, uric acid crystals in the urine must be looked for.

Third, the calculus must be recovered and analyzed.

Prophylaxis. The prevention of recurrence, rather than the prevention of the initial stone, is the problem. Certain general measures should be prescribed for all patients: hydration, mobilization and elimination of infection.

Forcing fluids up to amounts of 4000 cc. per day is probably the single most valuable preventive measure. Micelle formation is inhibited and precipitation is arrested. In addition, any existing nidi or small stones tend to be washed out by the increased urinary flow. For example, Suby has evidence that recurrence in a solitary kidney, which has twice the normal output of urine, is less frequent than when both kidneys are present. Prien's suggestion is to start the day with twenty pennies in one pocket and to transfer one for each glass of water taken, until at the end of the day all are in the other pocket.

Mobilization can be a critical factor. Bed rest promotes resorption of calcium from the skeleton so that excess urinary excretion results. It also enhances stasis, so that the urinary tract is more susceptible to infection and any embryonic stone stays behind to grow larger.

Elimination of the infection which is usually present at the time the stone is removed is most important but is often not easily done. Urea-splitting organisms, which make the urine alkaline and so increase the deposition of calcium phosphate and carbonate, are introduced by retention catheters. Low dosage chemotherapy, irrigation with Suby's solution G, a buffered citric acid solution in which calcium is soluble, and frequent change of catheters all help.

In addition, plain roentgenograms or intravenous urograms should be made regularly and the urine should be examined periodically for pus and organisms.

More specific measures may be needed in certain cases, especially if recurrence is rapid. Recurrence of calcium phosphate stones is slowed by a low calcium intake

Figure 15. The sequelae of stasis.

but a low phosphorus-Basaljel or sodium phytate regimen may be required. Phytate's benzene ring with phosphate radicals forms a complex with calcium and so reduces its availability. Acidification by an acid-ash diet is disappointing for, although calcium is more soluble in an acid urine, it is likewise absorbed more readily from the acidified gastrointestinal tract. Salicylate therapy, thought to promote protective glucuronide excretion, has not proved effective. Calcium oxalate stones are inhibited by measures similar to those outlined above, reduction in oxalate intake does not seem to reduce the formation of stones.

Uric acid stones are inhibited in an alkaline urine, maintained by the ingestion of sodium or potassium citrate. A similar program is applicable for cystine stones, although it is somewhat less effective.

Clinical Findings. The symptoms of a urinary tract stone are limited to the pain which the stone causes, to the secondary changes brought about by actual irritation by the stone, to the symptoms associated with the accompanying infection and to the train of symptoms of renal failure due to occlusion by the stone.

Pain is caused by a stone when it moves and irritates the surfaces or when it actually blocks the outflow of urine, causing colic if in the ureter or distention of the renal capsule and pelvis if at the ureteropelvic junction. Since many stones grow without causing much local irritation and do not move from the site where they were originally formed, a high percentage of calculi give no symptoms of their presence, although occasionally a large calculus in the renal pelvis or in the bladder may cause direct pain when the patient moves suddenly or is jarred.

Hematuria is common, resulting from contact of the stone with the lining of the pelvis or ureter. Microscopic blood will be found in almost all patients with urinary tract stone.

Infection causes the usual symptoms of acute pyelonephritis. Very often, after subsidence of these acute attacks, low-grade pyelonephritis is fostered by the stones. If the stone almost completely obstructs the kidney, this low-grade infection can be extremely debilitating. Since the symptoms do not point directly to the kidney, the diagnosis is often delayed.

Dysuria is caused by reflex reaction of the bladder to ureteral hyperactivity from

the ureteral calculus, by actual irritation of the stone in the bladder itself or by the secondary infection. Occasionally the stone may act as a ball valve, intermittently occluding the urethral outlet. This may be so marked that the patient must assume acrobatic positions to empty his bladder.

Renal failure is occasionally associated with a urinary tract calculus. The classic example is a calculus obstructing the ureter of a solitary kidney. Overdosage of sulfonamides without adequate alkalinization of the urine has resulted in chemical calculi obstructing the tubules or obstructing the renal pelvis and ureters. It is also possible for acute obstruction of one kidney to act reflexly through the sympathetic nerves and cause renal shunt and anuria on the contralateral side. While this has not been demonstrated clinically, there are good experimental reasons for its occurrence.

Diagnosis. The history may or may not be characteristic. Physical examination may reveal enlargement or tenderness of one kidney. Rarely, by combined rectal and abdominal palpation, a calculus may be felt in the bladder. Examination of the urine will reveal hematuria in a high percentage of cases. It is best to see the patient during an attack in order to reveal this clinical finding. Of course, if the urinary tract is infected as well, there will be pus and bacteria in the urine. Decrease in total renal function, while not diagnostic, is of great value in assessing the damage done by the stone. A plain film is important in the diagnosis of urinary tract calculi since by knowing the usual position of the ureter and by visualizing the outline of the kidney one may make a fairly reasonable guess as to whether the calcification lies within or outside the urinary tract. In addition, familiarity with the x-ray shadow cast by stones will help differentiate them from phleboliths, calcified mesenteric nodes and foreign bodies within the gastrointestinal tract. Since about 6 per cent of renal calculi cast no shadow, the roentgenogram cannot be used to rule them out completely.

Intravenous pyelography is of great value in confirming the location of densities seen on the plain film and in assessing the degree of obstruction. Whereas urethral calculi are best identified and localized by palpation and the use of a metal sound which grates on the stone, bladder stones are suspected by examination of the plain film and are diagnosed absolutely by cystoscopic inspec-

tion. *Calculi in the ureter* are localized partly by intravenous urography and partly by retrograde catheterization. An occasional valuable help in nonopaque calculi is the use of a catheter prepared with a soft wavy tip so that it will receive a scratch upon passing the stone. Renal calculi will be found to lie within the shadow of the calices by intravenous and retrograde pyelography and, in addition, information gained regarding relative function by the retrograde study will help decide whether removal of the stone or removal of the kidney is the proper course.

Routine examination of the urine, done before operation for appendicitis, may reveal red blood cells, which suggests that a search for ureteral calculi should be made. Occasionally, however, an appendix lying near the course of the ureter will so irritate the ureter that hematuria, perhaps even with pyuria and bacilluria, may occur. If a plain film is obtained and intravenous urography is performed, a differentiation of the ureteral calculus and the abnormally located appendix can be made. The symptoms of a ureteral calculus may also be mimicked by a blood clot passing down the ureter from tumors or tuberculosis of the kidney. A tumor of the renal pelvis or ureter may intermittently obstruct the outlet so that renal colic occurs. A plain film and retrograde study will help to rule out these diseases. Intercostal neuritis, especially of branches of the twelfth thoracic and first lumbar nerves, may occasionally mimic a ureteral calculus until the typical skin lesion occurs.

TREATMENT

Urinary tract calculi may be managed expectantly, by manipulative procedures or by open operation. Attempts to dissolve calculi have met with little success so far.

Urethral calculi may occasionally be manipulated from the urethra by fairly simple means, especially if they are not too large and are situated distally in the urethra.

Vesical calculi are usually retained ureteral stones. A stone able to pass through the ureter should be able to pass out through the urethra unless some obstruction is present at the vesical neck. Treatment of a bladder stone must then be accompanied by treatment of the obstructing lesion. If prostatic hypertrophy is the factor involved, then the stone may be removed at the time of prostatectomy.

The first crushing instrument was de-

veloped over a hundred years ago. The lithotrite is passed through the urethra to grasp the stone blindly and elevate it from the floor of the bladder and crush it. This process can be repeated until the fragments are small enough to be evacuated through a large-bore sheath. Numerous irrigating and visual modifications of the lithotrite have been developed, but they all have the fundamental disadvantage that addition of lenses or irrigating tube weakens their structure so that they are subject to bending and breaking. Such unfortunate occurrences can leave a foreign body in the bladder that is worse than the original stone. Stones larger than 2 inches in diameter or stones formed upon a foreign body too large to be withdrawn through the urethra, and some large stones of extreme density, should not be subjected to litholapaxy but are best removed suprapubically by open operation.

Ureteral calculi can be treated in several ways. One may (1) wait for the stone to pass of its own accord, urging it along by suitable measures, (2) introduce instruments through the urethra and ureter to manipulate and withdraw the calculus or (3) perform open operation. The factors which influence judgment are: (1) Size of the stone. A stone greater than 1 cm. in diameter, especially if situated in the upper ureter, probably should be attacked surgically. One should avoid operation for small stones, especially small renal stones, because they may move and be difficult to locate. They can be expected to pass spontaneously. (2) The position of the stone in the ureter. A stone arrested in the upper ureter has farther to go and less chance of passage. Therefore, operation may be warranted for a small stone high in the ureter, a stone which would be expected to pass if it lay in the lower ureter. In the upper ureter manipulation is more difficult and hazardous, whereas operation is easier. (3) The duration of impaction. If a stone shows signs of progression down the urinary tract, its passage can be awaited. If the stone has become impacted in one area and has not moved over a long period, it will need manipulation or operation for removal. The long period of nonmovement is itself an indication that the stone is too large for the ureter at that point. In addition, after a time in one location, the stone causes irritation and ureteral thickening which obstruct its passage. (4) The presence of infection. If infection is present above the stone, then

waiting for spontaneous passage or manipulative treatment should be persisted in for only a brief period. Early open operation is desirable for these patients, since pyelonephritis or multiple cortical abscesses can not only severely damage the kidney but may prove fatal. (5) The function in the opposite kidney. If the contralateral kidney has less than normal function, one is not justified in prolonging expectant and manipulative procedures. Delay may be enough to push the patient into renal failure. (6) The general condition of the patient. Judgment must be used in choosing the least traumatic and most certain method of removal of the stone in patients ill from sepsis or debilitation.

Expectant treatment is begun by forcing fluids to increase the rate and volume of ureteral peristalsis. This in turn increases the possibility that the stone will be passed. Ambulation of the patient also accelerates movement of the stone. Morphine is administered in adequate dosage to control the pain of ureteral colic. Urinary antibacterial agents may be given to decrease the likelihood of infection. The patient must be observed closely for pain or tenderness in the flank and should be studied by intravenous urography for evidence of ureteral blockage which would produce hydronephrosis and renal damage.

Manipulative treatment is reserved for stones less than 1 cm in diameter in the lower ureter, which have not been impacted too long. The loop catheter, which contains a fine steel wire so that traction on the wire produces a loop at its tip, is passed to the renal pelvis and the loop is formed. The loop is slowly drawn down until the stone is engaged and is pulled down intermittently for from twelve to twenty-four hours in order to withdraw the stone gradually. Special wire basket extractors may be used instead of the looped catheter.

If the stone lies just outside the bladder, it may be encouraged to drop in if the orifice is incised with a cautery or scissors.

Operative treatment is indicated for upper ureteral stones, which are approached through the flank, and for lower stones, which are removed through the lower abdomen. If nephrectomy is necessary because the kidney is severely damaged by hydronephrosis or pyonephrosis, the ureter must be removed down to the site of the stone, since a stone left in a blindly ending ureter will maintain infection, producing intermittent pyuria which can infect the opposite

kidney. Ureterolithotomy for a stone in the terminal portion of the ureter may be difficult because this area lies so deep in the pelvis. After the stone is removed, the incision in the ureter is left open and adequate drainage provided to the area. The ureter will quickly heal if obstruction is not still present.

Renal calculi, if small, in patients who give a history of having passed gravel previously, should be treated conservatively, since they may be expected to pass spontaneously. Conservative treatment is appropriate if renal damage is not evident, if symptoms are few, the stones are small and there is no evidence of renal damage. Surgical treatment also should probably be avoided in those patients who rapidly reform stones after operation and in patients who have cortical calcifications in conjunction with hyperparathyroidism. However, renal stones of sufficient size to cause symptoms, promote infection or cause renal damage through irritation or obstruction should be removed by open operation. The fact that nephrectomy has been found necessary in more than 30 per cent of patients with renal calculi shows that diagnostic procedures were not applied early enough or astutely enough. The decision as to whether the stone should be removed by pyelotomy or nephrotomy, incising through the renal cortex, or whether the entire kidney should be removed by nephrectomy will rest on a number of findings: (1) the condition of the opposite kidney, (2) the degree of damage in the affected kidney and (3) the size of the stone. Stag-horn calculi requiring extensive nephrotomy are occasionally best treated by nephrectomy, whereas a large pelvic stone can often be removed by the less damaging operation of pyelotomy. If stones are present bilaterally, one must be more conservative, for the incidence of recurrent calculi is high. For instance, large bilateral stag-horn calculi in an older patient should perhaps be left alone since the formation of such large calculi in itself indicates sufficient renal function to provide this copious excretion of salts and since operation is so damaging to the kidney. In a younger patient, however, bilateral nephrotomy with removal of the stag-horn calculi and careful resuturing of the calices and renal parenchyma is better, since these patients after operation have a greater life expectancy than they would if the stones were left in place. If stones lie in the ureter as well as

in the kidney, the lowermost stone should be attacked first, since ureteral stones are usually more damaging to kidney function than are renal stones.

RECURRENCE OF CALCULI

Renal stones recur in about 30 per cent of the patients upon whom nephrolithotomy has been performed. This recurrence rate is partly an indication of inadequate removal done without roentgenographic studies at the operating table and partly a measure of the continued action of the intrinsic factors which produced the stone in the first place. Meticulous care in removal, avoidance of encrustation on retention catheters and insistence on prophylactic procedures will be of aid in preventing recurrence.

Prophylaxis Against Occurrence and Recurrence of Urinary Tract Calculi. Measures to prevent recurrence are obvious from a study of the factors in the formation of renal calculi which are listed in Table 3. Obstruction must be treated by dilation or by operative procedures and infection must be eradicated, especially that due to urea-splitting organisms. Hyperparathyroidism must be treated by removal of the parathyroid adenoma. Patients with cystinuria or with uric acid stones can prevent recurrence of the stones by maintaining an alkaline urine. Patients who are immobilized must be moved about as much as possible, even by using a tilting bed if necessary. The factors involved in crystalloid-colloid balance are best maintained by a high water intake which so dilutes the crystalloids that precipitation is less likely. If sulfonamide drugs are being administered in high dosages, fluid intake should be adequate and the urine made alkaline. Foods which contain calcium should be avoided in patients with calcium stones. The value of the acid-ash diet is in doubt and the high proportion of meat necessary in carrying out this diet increases the excretion of urea, which in turn may furnish an excellent medium for the growth of the urea-splitting organisms, especially if they are so firmly established that the urine cannot be rendered acid. A low phosphorus-aluminum hydroxide or a phytate regimen may be needed if simple measures fail.

DISSOLUTION OF STONES

Instillation into the bladder of Suby's solution G, essentially a buffered citric acid solution, through a retention catheter has dissolved some vesical calculi, but usually

litholapaxy or open operation is better because much less hospitalization is required and the results are more certain. In the treatment of recurrent urinary tract calculi, solution G can be used immediately after operation when a nephrostomy tube is in a kidney which still contains calcareous remnants. It is also valuable in postoperative patients in whom an alkalinizing, urea-splitting organism causes rapid incrustation of the nephrostomy tube and of the renal pelvis. The attempt at dissolution of stones by solution G supplied through ureteral catheters has almost uniformly met with failure because, even though solution G dissolves the crystalloids on the surface of the stone, it cannot dissolve the layer of organic material forming the matrix of the stone. Attempts at adding urease and other proteolytic enzymes have not been successful because of the inability of weaker solutions of these substances to dissolve the organic matrix and because of the tendency of the enzymes to attack the renal parenchyma as well as attack the stone.

Urinary calculi form by precipitation upon a nidus of salts unstably present in the urine. Prevention and treatment are thus directed at assisting the urinary tract to rid itself of these foreign bodies by removing obstructions, and at reducing the concentration of dissolved crystalline substances discharged through the kidneys by diet, by high fluid intake, or by reducing the availability of these substances by eliminating infection, altering the pH of the urine or adding compounds with a particular affinity for the salts.

Surgical or instrumental removal of an established stone precedes the prophylactic measures, since they will not be effective in the presence of obstruction or infection.

NEOPLASMS OF THE URINARY TRACT

TUMORS OF THE URETHRA

The majority of tumors of the urethra arise after periods of inflammation. In women, nonmalignant masses are by far the more common. In men, any urethral mass must be assumed to be malignant until tissue examination proves it to be otherwise.

Diagnosis is made by direct examination of the urethra through a panendoscope in the patient who complains of urethral symptoms such as bleeding, frequency, urgency, dysuria, urethral discharge and decrease in caliber of the stream.

waiting for spontaneous passage or manipulative treatment should be persisted in for only a brief period. Early open operation is desirable for these patients, since pyelonephritis or multiple cortical abscesses can not only severely damage the kidney but may prove fatal. (5) The function in the opposite kidney. If the contralateral kidney has less than normal function, one is not justified in prolonging expectant and manipulative procedures. Delay may be enough to push the patient into renal failure. (6) The general condition of the patient. Judgment must be used in choosing the least traumatic and most certain method of removal of the stone in patients ill from sepsis or debilitation.

Expectant treatment is begun by forcing fluids to increase the rate and volume of ureteral peristalsis. This in turn increases the possibility that the stone will be passed. Ambulation of the patient also accelerates movement of the stone. Morphine is administered in adequate dosage to control the pain of ureteral colic. Urinary antibacterial agents may be given to decrease the likelihood of infection. The patient must be observed closely for pain or tenderness in the flank and should be studied by intravenous urography for evidence of ureteral blockage which would produce hydronephrosis and renal damage.

Manipulative treatment is reserved for stones less than 1 cm. in diameter in the lower ureter, which have not been impacted too long. The loop catheter, which contains a fine steel wire so that traction on the wire produces a loop at its tip, is passed to the renal pelvis and the loop is formed. The loop is slowly drawn down until the stone is engaged and is pulled down intermittently for from twelve to twenty-four hours in order to withdraw the stone gradually. Special wire basket extractors may be used instead of the looped catheter.

If the stone lies just outside the bladder, it may be encouraged to drop in if the orifice is incised with a cautery or scissors.

Operative treatment is indicated for upper ureteral stones, which are approached through the flank, and for lower stones, which are removed through the lower abdomen. If nephrectomy is necessary because the kidney is severely damaged by hydronephrosis or pyonephrosis, the ureter must be removed down to the site of the stone, since a stone left in a blindly ending ureter will maintain infection, producing intermittent pyuria which can infect the opposite

kidney. Ureterolithotomy for a stone in the terminal portion of the ureter may be difficult because this area lies so deep in the pelvis. After the stone is removed, the incision in the ureter is left open and adequate drainage provided to the area. The wound will quickly heal if obstruction is not still present.

Renal calculi, if small, in patients who give a history of having passed gravel previously, should be treated conservatively, since they may be expected to pass spontaneously. Conservative treatment is appropriate if renal damage is not evident, if symptoms are few, the stones are small and there is no evidence of renal damage. Surgical treatment also should probably be avoided in those patients who rapidly reform stones after operation and in patients who have cortical calcifications in conjunction with hyperparathyroidism. However renal stones of sufficient size to cause symptoms, promote infection or cause renal damage through irritation or obstruction should be removed by open operation. The fact that nephrectomy has been found necessary in more than 30 per cent of patients with renal calculi shows that diagnostic procedures were not applied early enough or astutely enough. The decision as to whether the stone should be removed by pyelotomy or nephrotomy, incising through the renal cortex or whether the entire kidney should be removed by nephrectomy will rest on a number of findings: (1) the condition of the opposite kidney, (2) the degree of damage in the affected kidney and (3) the size of the stone. Stag-horn calculi requiring extensive nephrotomy are occasionally best treated by nephrectomy, whereas a large pelvic stone can often be removed by the less damaging operation of pyelotomy. If stones are present bilaterally, one must be more conservative, for the incidence of recurrent calculi is high. For instance, large bilateral stag-horn calculi in an older patient should perhaps be left alone since the formation of such large calculi in itself indicates sufficient renal function to provide this copious excretion of salts and since operation is so damaging to the kidney. In a younger patient, however, bilateral nephrotomy with removal of the stag-horn calculi and careful resuturing of the calices and renal parenchyma is better, since these patients after operation have a greater life expectancy than they would if the stones were left in place. If stones lie in the ureter as well as

the present time, it is reasonable to insist that the patient take large quantities of water to dilute the carcinogens.

Pathology. The most common tumor of the bladder is papillary carcinoma. It is simplest to think of vesical carcinomas as if they arose in successive stages. The first manifestation is a simple papilloma, with a narrow stalk and delicate fronds. On microscopic examination, one sees no evidence of malignant change in the fronds, stalk or in the base where the tumor is attached to the bladder wall. These lesions may or may not progress to a malignant form. Increasing malignancy is signaled by thickening of the stalk and clubbing of the papillary fronds. Ulceration follows, with increasing infiltration by malignant cells at the base, first penetrating through the mucosa and submucosa, later invading the muscularis, and finally going through all layers of the bladder wall. It is not possible in the case of a small tumor to say definitely that it is non-malignant even after microscopic examination. It is therefore necessary to consider all papillary tumors of the bladder as potentially malignant and treat them accordingly.

The fact that bladder tumors may be multiple and recurrent makes careful follow-up cystoscopic examinations after treatment imperative.

Squamous cell carcinoma, although less common, is highly malignant. It is infiltrating from the onset and is usually unrecognized until the surface ulcerates. It is extremely hard grossly, and microscopically it

consists of squamous cells with or without cornification.

Symptoms. Hematuria is the presenting symptom in more than 77 per cent of these tumors. Often recurrent cystitis or dysuria will lead to cystoscopy and to discovery of the tumor. Ureteral obstruction is not rare, because the areas about the ureteral orifices are most commonly involved by tumor. A routine search for the source of the obstruction of the upper urinary tract and infection may reveal the presence of tumor.

Diagnosis. The diagnosis is made after cystoscopic examination. The bladder is inspected area by area in a routine fashion so that multiple tumors will not be overlooked. A biopsy of the tumor is made at the same time. The ideal excision for biopsy will include a portion of the base and some of the muscle, so that the degree of infiltration can be estimated. Bimanual palpation with the patient anesthetized must be performed in all large tumors to estimate the depth of infiltration and so determine operability.

Treatment. Small, pedunculated tumors are resected transurethrally with the resectoscope, which removes a portion of the submucosa and muscle underlying the tumor. The base is then thoroughly fulgurated with the high frequency current. Larger tumors which have been found to have penetrated into the muscle, but not to have extended through it, are treated by deep resection or preferably by partial cystectomy, or by total cystectomy with diversion of the urine. If the tumor has already infiltrated the walls

	C			RADICAL CYSTECTOMY, DEEP RADIATION; INJECTION	→

Figure 16 Relation of cell grade to depth of infiltration.

Pathologic Changes. Squamous cell carcinoma of the urethra is most common, occurring in more than 85 per cent of the cases.

Since the urethra is lined with transitional cell epithelium, metaplasia probably occurs initially. Urethral tumors are highly malignant and are likely to metastasize directly to the deep nodes, especially the iliac and pelvic nodes, without involving the superficial inguinal nodes. The process in the urethra extends along the urethral lumen and infiltrates the periurethral tissues, causing the symptoms of obstruction and local infection.

Clinical Course. The onset is insidious, with tumor and urethral stenosis appearing first, then extension with ulceration, formation of fistulas and hemorrhage and, last, infection and metastasis leading to cachexia and death.

Diagnosis. The disease is easily confused clinically with the common urethral stricture and periurethral abscess. Perhaps greater induration and more involvement of surrounding tissues will suggest the diagnosis of carcinoma. The fact that neoplasm, in contrast to stricture, is more common in the pendulous portion and more common in men in later years is an aid. Endoscopy will often help. Unfortunately, biopsy can be misleading, since often only the more superficial, inflammatory tissue is obtained.

Treatment. Urethral carcinoma needs radical treatment. Amputation of the penis high above the lesion should usually be followed by excision of the regional lymphatic drainage area. This means complete excision of the iliac and pelvic nodes. If such radical excision is not possible because of the advanced state of the disease, palliative radium or radiation therapy offers the patient little and may cause an increase in the stricture of the urethra which then responds very poorly to dilation.

In women, unless the lesion is very small, radiation is followed by recurrence.

TUMORS OF THE BLADDER

Classification. From a descriptive and etiologic point of view, the tumors may be divided into two groups by cell type:

I. Epithelial

A. Carcinoma

1. Papillary (90 per cent)

2. Squamous (5 per cent)

3. Adenocarcinoma (rare)

II. Mesothelial and other (5 per cent)

A. Sarcoma

In addition to cell type, the tumors may be graded by degree of differentiation (Fig. 16). Grade 1: Histologically benign papilloma with cellular uniformity and little nuclear abnormality or mitotic activity. Grade 2: Papillary tumors which show nuclear abnormalities and more than a rare mitotic figure. Grade 3: Papillary tumors exhibiting atypism and excessive mitotic activity. Grade 4: Frankly anaplastic tumors.

An additional and clinically useful classification is based on depth of infiltration as gauged by resection biopsy and by bimanual palpation under anesthesia (Fig. 16). The more benign tumors confined to the mucosa and submucosa of the bladder are classified group A. Group B₁ includes those infiltrating through less than half of the muscle and B₂ through more than half. In group C, the muscle layer has been traversed and perivesical involvement is present. The A and B₁ tumors, which are not palpable bimanually, are potentially curable by complete surgical removal.

Etiology. Workers in the aniline dye industry have a high incidence of bladder tumors, due to ingestion of carcinogenic substances which, on excretion, come in contact with the lining of the urinary tract. Because of the similarity between, and often concomitant occurrence of, tumors of the bladder, ureters and renal pelvis and because of the frequent recurrence of similar tumors at areas distant from the site of the initial tumor, we might assume that a carcinogen is present in the urine.

The administration of β -naphthylamine orally to dogs produces bladder tumors. If the ureters are transplanted to the bowel, no tumors form in the bladder but may appear in the ureter. If half the bladder is isolated from the urinary flow, no tumors form, but they will grow if they are implanted there. It has also been shown that it is the unconjugated metabolite of β -naphthylamine, 2-amino-1-naphthol, which produces the experimental tumors. Patients with spontaneous bladder tumors have excessive amounts in the urine of the metabolic products of tryptophan which resemble 2-amino-1-naphthol. In normal individuals these substances occur in small amount and are excreted, conjugated and detoxified with a glucuronide. Urine from patients with bladder tumors contains large amounts of glucuronidase which, splitting the detoxified substance, releases the active carcinogen.

It may be then that administration of a conjugating substance will be practical. At

done, in which filling defects are sought. Filling defects may come from nonopaque calculi and blood clots as well as from tumor. Neoplasms of the renal parenchyma may be difficult to differentiate from renal cysts. Calcification, which is typical of these tumors, can be an aid in diagnosis. When blood streams from one ureteral orifice on cystoscopy, this is a great help in localizing the lesion. All patients with urinary bleeding should have immediate cystoscopy if the source is not obvious.

Treatment. Surgical approach to the kidney must not be made until complete investigation has established the diagnosis, since exposure of the kidney rarely allows diagnosis and incision of the kidney for biopsy may allow spread of the tumor. In children, a transperitoneal approach is best since the renal pedicle can be ligated and divided before mobilization of the kidney is carried out to reduce the chance for tumor embolism. In adults, it is generally easier to mobilize the kidney from the usual lumbar approach, but care must be taken to manipulate the kidney as little as possible before ligating the pedicle and to remove as much of the perirenal fat as possible. If the tumor is growing into the renal vein and vena cava, it is worth while to attempt to remove these prolongations even though the prognosis is grave.

Prognosis. The late mortality after nephrectomy for renal carcinoma is extremely high. Death usually occurs within a year but may occur after five years. The over-all five-year rate of cure is about 10 per cent. Irradiation cannot substitute for nephrectomy. Radiation therapy, however, has a place in late palliation of renal carcinoma and is useful in Wilms' tumors. In these cases preoperative irradiation will reduce the size of the tumor and facilitate its removal and postoperative irradiation will give a higher percentage of cures than operation alone.

Tumors of the urinary tract are suspected when hematuria occurs, but they may instead produce obstruction and secondary infection. Least often are they discovered as palpable or visible masses.

Diagnosis of renal, ureteral and vesical tumors rests on instrumental and radiologic localization in order that they may be excised surgically. The prognosis in general is poor because bleeding and obstruction are late symptoms.

NEUROGENIC BLADDER

Two components of the bladder, smooth muscle and nerves, are concerned in the functional anatomy of neurogenic bladder.

The smooth muscle of the detrusor has the intrinsic quality of all smooth muscle in that it maintains tone even after all motor nerves to the bladder are blocked. An example of this persistence of tone is seen after spinal anesthesia. The characteristics of the bladder, whether innervated or denervated, are such that during filling a constant pressure is maintained, each increment of urine being accommodated by appropriate relaxation. Alterations in this property of accommodation occur after overstretching of the bladder or in instances in which there are too many motor impulses to the bladder, usually as a result of a short circuit of the reflex arc by injury or with excessive sensory stimuli from the bladder. In Figure 17 are illustrated the sources of nervous impulses to and from the bladder. The supply is double: parasympathetic and somatic. The sympathetic nerves are an unimportant portion of the nerve supply. The parasympathetic supply constitutes the main reflex arc and is carried by way of the hypogastric plexus and the pelvic nerve. Stimulation causes contraction of the detrusor. Section first causes complete inability to empty the bladder, but later weak uncoordinated contractions of the detrusor occur with fasciculation and hypertrophy.

The somatic supply is carried through the pudendal nerve. Stimulation causes closure of the external sphincter, a striated muscle. Section results in relaxation of the external sphincter. Incontinence occurs only if both the internal sphincter and external sphincter are absent.

Physiology. Normal urination is accomplished in five phases: (1) cerebral release of inhibition, (2) detrusor contraction (parasympathetic), (3) relaxation of the internal sphincter (detrusor action), (4) relaxation of the external sphincter (somatic via pudendal) and (5) contraction of the external sphincter, bulb and perineal musculature at the termination of urination.

The reflex arcs involved in urination (Fig. 17) are (1) proprioceptive sensation from the filling of the bladder passes over the parasympathetic fibers of the pelvic nerve, by way of the hypogastric plexus, to the spinal cord and ascends by way of (2) the fasciculus gracilis to (3) consciousness in the sensory cortex, resulting in inhibition if

of the bladder, it is best to resect it as adequately as possible transurethrally and then treat it by radiation therapy. Papillomatosis, in which large areas of the wall of the bladder are dotted with small, fairly benign tumors, is now treated with cobalt-bead therapy. A bead of radioactive cobalt is placed in the geometric center of the bladder in a water-filled Foley bag, so that radiation is evenly distributed to the entire bladder mucosa. Contact irradiation by the way of suprapubic cystostomy, high voltage external irradiation and open resection with deep fulguration are seldom used at our clinic because of poor results and high morbidity. However, since the results of radical surgery in these patients have been disappointing, we have to keep an open mind regarding treatment.

TUMORS OF THE URETER AND RENAL PELVIS

Since tumors of the ureter and renal pelvis arise from the same transitional epithelium as do tumors of the bladder, the classification is essentially the same. More tumors of the ureter have been reported in recent years, indicating that they are less rare than formerly supposed.

Pathologic and Clinical Signs. The pathologic changes in transitional epithelium of the ureter and renal pelvis are similar to those which have been discussed under tumors of the bladder. The ureteral tumor as it grows usually produces obstructive symptoms with superimposed infection, but it may produce only hematuria, as does the pelvic papillary carcinoma. Diagnosis is made by pyeloureterography which will often show the characteristic filling defect. Because symptoms appear late, too often these cases are overlooked until the tumor is incurable.

Treatment. Ureteronephrectomy is necessary. The percentage of cure is relatively small because extension outside the ureter and pelvis occurs early, metastasizing to the bones and liver. Simple excision of a portion of the ureter for a small tumor will be applicable only with a solitary kidney.

TUMORS OF THE KIDNEY

Classification of Renal Parenchymal Tumors.

- I. Epithelial tumors
 - A. Adenoma
 - B. Carcinoma
- II. Tumors of connective tissue (sarcoma)

- III. Embryonal tumors (Wilms' tumor)
- IV. Rare tumors from adrenal rests (true hypernephromas)

Etiology. The origin of parenchymal tumors is unknown. The so-called embryonal (Wilms') tumor is of developmental origin.

Pathology. Adenomas are frequently found at autopsy. These are small benign tumors composed of papillary fronds or tubules.

Carcinoma of the kidney is the most common renal neoplasm. Since Crawitz first suggested that they arose from adrenal rests in the renal cortex, there has been much discussion of the origin of these tumors. His theory is no longer held to be valid, yet these tumors are still often called hypernephromas. Renal carcinoma is a more suitable term. Adenocarcinoma is the common form; it is made up of tubular overgrowth, either papillary or solid. The tumors are yellow, and hemorrhage and infarction are commonly seen. The typical cell is large and clear, resembling an adrenal cortical cell with a shrunken nucleus. The tumor invades the blood vessels early and metastasizes to the bones and lungs where it forms the typical cannon ball metastases, which are occasionally the first finding. Removal of the lung for a presumed primary tumor of that organ occasionally reveals the renal source; subsequent nephrectomy is carried out with occasional cure.

Embryonal carcinoma (Wilms' tumor) is the common renal tumor in children. On microscopic section these tumors show a variety of mature and immature cells, especially smooth muscle, glandular tissue and sarcomatous tissue usually of a spindle cell variety, as well as nervous tissue.

Symptoms. Unfortunately, when any of the classic triad of symptoms of renal carcinoma (hematuria, pain and tumor) is present, the lesion is often well advanced and difficult to cure. Hematuria is the initial symptom in about 40 per cent of the cases, but pain occurs first in 30 per cent and tumor in about 10 per cent. Tumor is the most frequent presenting symptom in children. Approximately a third of patients have all three symptoms at the time of initial examination. Neoplasm may be overlooked as a cause of hematuria because it may be transient; among 148 patients with hematuria from renal neoplasm, only one had hematuria lasting as long as fourteen days.

Diagnosis. If no vesical or urethral source of bleeding is found on cystoscopy and if the bleeding is total, a retrograde study is

function from the usual neurologic examination, but it is needed for correlation and to allow classification of the neurogenic bladder. It also offers a background for application of methods of therapy, particularly those employing blocking or sectioning of nerves.

2. Cystometry is done by measuring intravesical pressure during filling of the bladder. Although articles have been written proving statistically that the specific type of neurologic disturbance of the bladder cannot be determined by cystometry alone, the value of the procedure can be readily realized if it is considered as an additional means of determining the type and degree of disturbance, rather than as a single, independent and absolute diagnostic procedure. A normal cystometrogram is shown in Figure 18. It should be noted that with each 50 cc. increment of fluid there is accommodation by the bladder so that the pressure remains at a little above 10 cm of water pressure until bladder capacity is reached between 400 and 450 cc. At this time the patient is instructed to cease inhibition of his voiding reflex. He voids around the catheter.

3. Cystoscopy, or better, panendoscopy, with observation of the vesical neck and external sphincter, is a valuable adjunct in the diagnosis of neurogenic bladder. For instance, long-standing failure to relax the internal sphincter results in a collar of tissue at the vesical neck which is obstructive in itself. Spasm and lack of relaxation of the external sphincter are also observed and, in addition, any actual obstructive hypertrophy of the prostate in older patients may be observed at this time. The condition of the bladder wall, such as the degree and type of detrusor hypertrophy, may also be seen. Concomitant abnormalities are also noted, the principal one being vesical diverticula, which, of course, make restoration of normal bladder function more difficult.

4. Intravenous urography permits changes of the upper urinary tract secondary to disorders of the bladder to be seen and cystography will add information to and confirm the findings of cystoscopy. A cystogram made in conjunction with a urethrogram will allow detection of dilatation of the bladder neck such as is found with lesions of the cauda equina. In addition, ureteral reflux, which results in renal damage, is detected. Such a finding warns against the use of tidal drainage, since this will cause renal damage.

5. Determination of sphincteric (urethral) resistance is important in the diagnosis of imbalance of the bladder since voiding depends on a vesical pressure higher than the opposing urethral resistance. Normal values of urethral resistance are between 20 and 30 mm. of mercury, but often only the strength of the sphincteric contraction is measured since the patient cannot relax the reflexly contracted external sphincter. If the vesical imbalance is found to be due to increased urethral resistance, its location should be determined by urethrography and panendoscopy.

6. The function test is perhaps the most important of all, since normal bladder function depends on a correct balance between the forces of filling and expulsion against the resistance of the sphincters and urethra. The crucial test, therefore, is measurement of the vesical capacity and of the residual urine, since an adequately functioning bladder, normal or neurogenic, must have a capacity greater than 200 cc. and must allow retention of less than 30 cc. or no residual urine. These conditions are necessary if serious chronic infection is to be avoided. Anything short of this cannot be called an adequate bladder.

Treatment of Spinal Shock. After an injury to the spinal cord, almost regardless of site or degree, a period follows of absence of function or of reflex activity below the site of injury. During this period of spinal shock the bladder functions as a denervated organ. Since it is unable to empty itself

Figure 17.

necessary, thence to (4) the cerebral motor cortex and (5) down the lateral corticospinal tracts to (6) parasympathetic fibers by way of hypogastric plexus and pelvic nerve to (7) the detrusor.

It is important to recognize that this reflex arc can be deficient in any part, consequently, disease or trauma can produce an almost infinite variety of functional results. This fact, of course, makes it hard to formulate an exact classification, since the groups are actually continuous with each other.

In classifying the individual patient, the site and degree of the nerve lesion should

be determined first. This in turn will suggest the effect on the bladder. It is necessary to utilize all the historical information, neurologic data and urologic findings that can be obtained about the patient. Often the type of neurologic lesion is determined by its effect on bladder function. The examination of the individual patient should include the following procedures:

1 A neurologic examination should be performed to establish the level and severity of the lesion as it affects the sensory and motor components of the somatic structures. Little can be learned of the bladder and rectal

Table 4. Characteristics of Neurogenic Bladders

I. UNINHIBITED	II. AUTOMATIC (reflex)	III. AUTONOMOUS	IV. SENSORY (atonic)	V. MOTOR
SITE OF LESION (See Figure 17)

MANY SMALL CONTRACTIONS, NOT CONTROLLED BY PATIENT, ENDING IN STRONGER CONTRACTION AND VOIDING

Figure 19

because intrinsic detrusor tone is less than urethral resistance, the bladder distends with urine. If the distention persists, the result is a flaccid, atonic bladder. Consequently, the aim of immediate therapy after a spinal cord injury should be to prevent overdistention, which can be accomplished occasionally by intermittent catheterization, more commonly by retention catheterization, or even by suprapubic cystostomy. The last should be reserved for patients treated under conditions where sterile handling of urethral catheters is impossible. The catheter is connected either to a tidal irrigating apparatus set at a suitable level by cystometrographic determinations so that the bladder will fill without overdistention and be periodically emptied, or to a Y-tube arrangement with a water-filled Kelly bottle which allows manual filling and evacuation of the bladder at intervals. In addition, it is wise to begin prophylactic chemotherapy to reduce the chance of invasive infection, since it is impossible to keep the bladder sterile no matter what form of indwelling catheter is used or what antibiotic is given. As soon as the bladder regains tone and function becomes established the catheter can be removed. Removal of the catheter is part of the therapeutic procedure which will be discussed below.

A neurologic approach to vesical dysfunction recognizes three main areas for interference with nervous pathways from the bladder: the suprasegmental, which mainly concerns inhibition of lower reflexes, the

upper motor neuron, which concerns the long extravesical reflexes, release of which results in something like normal voiding, and the lower motor neuron, which means short extravesical and mainly intravesical reflexes which leave the detrusor to its own devices. These sites are usually involved by lesions cutting both sensory and motor pathways. If only sensory pathways are interrupted, the reflex arc is likewise broken and, similarly, if the motor pathways are cut, dysfunction results. It is obvious that all degrees and modalities can occur, but if these major groups are kept in mind, any particular case can be loosely classified (Table 4).

The uninhibited neurogenic bladder results from decreased cerebral inhibition of bladder reflexes. In the normal infant, urination occurs whenever vesical or other regional stimuli reach a sufficient height to act through an upper motor neuron reflex arc, but as the child grows older, bladder training allows the cerebral cortex to exercise an inhibitory effect over this simple reflex arc so that reflex emptying can be delayed. Inhibition is obtained first during the waking hours and subsequently becomes so patterned that it is present even during sleep and enuresis ceases.

In some children, however, the cerebral inhibitory control does not become developed, perhaps as a result of deficient pathways or from psychologic defect, and the child continues to have uninhibited contractions (Fig. 19). There is then urinary frequency during the daytime and enuresis at night. The characteristics of this type of bladder are normal or increased tone and decreased capacity without residual urine.

Two groups are recognized, a congenital group and an acquired one. In the congenital group, administration of atropine in dosage sufficient to atropinize a child, if effective, is diagnostic of the uninhibited neurogenic bladder and, in addition, is therapeutic. The acquired group, however, which is composed of individuals with cerebral or high cord damage is less susceptible to this form of treatment.

The automatic neurogenic bladder typically results from a complete transection of the cord at a level above the conus. It may also result from a disturbance of the suprasegmental arc which simulates transection of the cord. The result is a reflex arc running from the bladder to the sacral cord, synapsing and running back down to the bladder. The bladder, then, is organ con-

balancing urethral resistance against intravesical pressure. For emptying to occur, the ineffective detrusor contractions, supplemented by the pressure of the abdomen and the hand, must overcome urethral resistance. If urethral resistance is too high, retention of urine will result. On the other hand, if urethral resistance is too low, incontinence occurs.

Several measures have been proposed to decrease urethral resistance, since the strength of detrusor contraction cannot be affected directly by therapy, even by such agents as the parasympathomimetic drug Urecholine.

Pudendal nerve block and section, either unilateral or bilateral, will cause partial paralysis of the external sphincter. Transurethral resection of the prostatic urethra, especially when definite obstructive elements are seen with the panendoscope, will quantitatively reduce urethral resistance. Often three or four resections must be done to secure a good result since initial overenthusiasm can result in incontinence.

The *sensory neurogenic bladder* occurs after interruption of the sensory side of the reflex arc. Tabes dorsalis, occasionally pernicious anemia and multiple sclerosis, and syringomyelia are followed by this dysfunction. The patient does not know when his bladder is full because the afferent stimuli are cut off, so that, after a time, gross overdistention occurs, which results in atony. This atonic bladder devoid of motor power is the end result of the sensory defect. The bladder has a large capacity and urination occurs by overflow during straining. Incontinence often brings these patients to the doctor. They are able to empty their bladders only by forceful abdominal pressure and manual compression. A cystometrogram would show a low filling pressure with a very large capacity and no contractions of any sort. Cystoscopically, fine trabeculations are seen. The neck of the bladder is open and relaxed, as are the other portions of the detrusor. The external sphincter is not involved by the atony, so that its resistance is the cause of the retention of urine and overflow incontinence.

The object of treatment is primarily preventive. If the patients are seen early, before bladder tone is destroyed, they can be instructed to void at predetermined intervals, perhaps every two to three hours. Their bladders then will not become overdistended. After overdistention and atony have

occurred, the object of therapy can only be to reduce the amount of residual urine and hope for return of bladder tone. The patient should be instructed to strain at each voiding and supplement the straining by manual pressure on the bladder. Urecholine may be of some assistance in increasing detrusor activity. In very severe cases a period of drainage by an indwelling catheter will occasionally reduce capacity to a more normal level and restore some tone. The fundamental disease process should be treated. Transurethral resection of the bladder neck is of little value to these patients since the bladder neck is already widely open. Section of the pudendal nerve, either unilaterally or bilaterally, in certain cases will promote reduced urethral resistance because of partial paralysis of the normally active external sphincter and so will decrease the amount of residual urine.

The *motor neurogenic bladder* is the result of loss of the motor side of the reflex arc. It is most commonly seen after poliomyelitis in adults. Sensation is normal so that distention is painful, but overdistention occurs because the bladder is unable to contract as a result of loss of efferent stimuli to the detrusor. If catheter drainage is not instituted, overdistention and atony will result.

In the immediate care of the paralyzed bladder the first aim should be to prevent atrophy resulting from overdistention by allowing catheter drainage; second, to avoid and repress infection, and, third, to reduce

Figure 21.

Figure 20.

trolled by a simple reflex. The lesions which cause this syndrome are usually injuries to the thoracic or lumbar cord which result in paraplegia.

The diagnosis of automatic neurogenic bladder rests upon locating the site and degree of injury and upon determining the type of bladder which results. The bladder empties by reflex activity arising either from intrinsic stimuli from the bladder wall itself or from extrinsic stimuli which provoke mass movement. These patients have no real sensation of vesical filling, but the increasing size of the bladder as the urine accumulates produces sensations within the abdomen which they may interpret as a full bladder. Urination occurs without warning as soon as the reflex arc is closed, by summation of afferent stimuli.

Two major types of automatic bladders are recognized. The more usual is the spastic type, the other is the so-called normal reflex neurogenic bladder. The former is seen in patients with spasticity of the extremities. It is characterized by small capacity with more or less residual urine. Since urination is of necessity frequent because of the spasticity and small capacity, urination is precipitant and inconvenient (Fig. 20). The goal of therapy is a so-called normal reflex neurogenic bladder. If this is obtained, bladder capacity may be as high as 300 cc. Visceral sensation of bladder filling may be enough to give the patient opportunity to reach a convenient place for voiding. Residual urine is low.

The therapeutic aim is first to remove all

irritative foci, since the bladder is a purely reflex organ with the sensory stimuli arising within the bladder wall itself, both from the mucosa and from the muscle, as a stretch reflex. Bladder infection and calculi increase the sensory component of the reflex arc and thereby cause increased stimuli for contraction.

A patient is observed over a period of months and then restudied to learn what sort of bladder function will result from these simple measures. If spasticity persists, blocking of the sensory nerve impulses is necessary and may be accomplished either by alcohol block or by sectioning the sacral roots. Intradural alcohol injection of the lower spinal cord blocks all long reflexes and produces an autonomous neurogenic bladder. The result is greater capacity and relative freedom from the inconvenient reflex voiding of the automatic bladder. A more direct approach is to block the sensory roots of the third, fourth and fifth sacral nerves to cut off the sensory components arising from the irritable bladder and so interrupt the reflex arc. The bladder is then free to relax and to attain a normal capacity. In addition, the irritative stimuli arising from the posterior urethra are cut off, releasing the reflex spasm of the sphincter. Thus, sphincter tone is more nearly normal. These procedures may assist patients with automatic bladders to regain almost normal control.

The *autonomous neurogenic bladder* results from section of the cauda equina and conus, usually by trauma, but occasionally by inflammatory lesions and often from such congenital anomalies as meningocele and spina bifida. In contrast to a lesion across the spinal cord above the conus, a lesion through the cauda equina leaves the bladder autonomous (Fig. 21), possessing little or no outside reflex arc. It acts merely by the intrinsic reflex arc through the detrusor ganglia.

Sensation is diminished and coordinated reflex stimulus to the detrusor is absent. The bladder fills against the intrinsic detrusor tone and urination is irregular and incomplete. Depending on the degree of resistance at the vesical neck, the patient will be able to void more or less of the bladder contents by increasing abdominal pressure or by the use of manual pressure over the bladder. The capacity of the bladder may be as high as 350 cc., but the residual urine is, of course, also quite high.

Treatment of these patients is directed at

balancing urethral resistance against intravesical pressure. For emptying to occur, the ineffective detrusor contractions, supplemented by the pressure of the abdomen and the hand, must overcome urethral resistance. If urethral resistance is too high, retention of urine will result. On the other hand, if urethral resistance is too low, incontinence occurs.

Several measures have been proposed to decrease urethral resistance, since the strength of detrusor contraction cannot be affected directly by therapy, even by such agents as the parasympathomimetic drug Urecholine.

Pudendal nerve block and section, either unilateral or bilateral, will cause partial paralysis of the external sphincter. Transurethral resection of the prostatic urethra, especially when definite obstructive elements are seen with the panendoscope, will quantitatively reduce urethral resistance. Often three or four resections must be done to secure a good result since initial overenthusiasm can result in incontinence.

The *sensory neurogenic bladder* occurs after interruption of the sensory side of the reflex arc. Tabes dorsalis, occasionally pernicious anemia and multiple sclerosis, and syringomyelia are followed by this dysfunction. The patient does not know when his bladder is full because the afferent stimuli are cut off, so that, after a time, gross overdistention occurs, which results in atony. Thus atonic bladder devoid of motor power is the end result of the sensory defect. The bladder has a large capacity and urination occurs by overflow during straining. Incontinence often brings these patients to the doctor. They are able to empty their bladders only by forceful abdominal pressure and manual compression. A cystometrogram would show a low filling pressure with a very large capacity and no contractions of any sort. Cystoscopically, fine trabeculations are seen. The neck of the bladder is open and relaxed, as are the other portions of the detrusor. The external sphincter is not involved by the atony, so that its resistance is the cause of the retention of urine and overflow incontinence.

The object of treatment is primarily preventive. If the patients are seen early, before bladder tone is destroyed, they can be instructed to void at predetermined intervals, perhaps every two to three hours. Their bladders then will not become overdistended. After overdistention and atony have

occurred, the object of therapy can only be to reduce the amount of residual urine and hope for return of bladder tone. The patient should be instructed to strain at each voiding and supplement the straining by manual pressure on the bladder. Urecholine may be of some assistance in increasing detrusor activity. In very severe cases a period of drainage by an indwelling catheter will occasionally reduce capacity to a more normal level and restore some tone. The fundamental disease process should be treated. Transurethral resection of the bladder neck is of little value to these patients since the bladder neck is already widely open. Section of the pudendal nerve, either unilaterally or bilaterally, in certain cases will promote reduced urethral resistance because of partial paralysis of the normally active external sphincter and so will decrease the amount of residual urine.

The *motor neurogenic bladder* is the result of loss of the motor side of the reflex arc. It is most commonly seen after poliomyelitis in adults. Sensation is normal so that distention is painful, but overdistention occurs because the bladder is unable to contract as a result of loss of efferent stimuli to the detrusor. If catheter drainage is not instituted, overdistention and atony will result.

In the immediate care of the paralyzed bladder the first aim should be to prevent atrophy resulting from overdistention by allowing catheter drainage; second, to avoid and repress infection; and, third, to reduce

Figure 21.

the possibility of stone formation by recommending ambulation, irrigation and a high fluid intake.

In later care, the establishment of the optimum reflex activity must be sought; it often occurs only after six months or longer.

Testing allows differentiation of the automatic bladder, which results from the higher spinal cord lesion, from the autonomous bladder secondary to injury of the cauda equina. But the final goal is balance and the final question is what can the bladder do?

For example, a patient with a high lesion voids small amounts frequently. His residual urine is low, but his capacity is also low and interpretation of the cystometrogram indicates a quick voiding reflex after small increments during filling. This is an automatic neurogenic bladder. To achieve balance, the bladder must be calmed by reducing afferent sensations which set off the premature reflex activity. This can be done either by decreasing infection in the bladder and removing stones, or by blocking the afferent nerves by sacral nerve block or subarachnoid alcohol block. If residual urine persists, a transurethral resection of the bladder neck will reduce urethral resistance and help achieve balance.

For another example, a patient suffers a low lesion in the cauda equina resulting in an autonomous neurogenic bladder. He voids by straining, but empties his bladder only incompletely. Interpretation of the cystometrogram indicates that the capacity is good, but adequate voiding pressure is reached only by abdominal compression and straining. To achieve balance in this case urethral resistance must be decreased. Pudendal block, interrupting the somatic nerves to the external sphincter, may help. More often, transurethral resection of the bladder neck performed in stages so that total incontinence does not result will achieve balance between the reduced vesical pressure and the surgically reduced urethral resistance.

THE MALE REPRODUCTIVE SYSTEM

By HENRY M. WEYRAUCH, M.D.

HENRY M. WEYRAUCH was born in a small village which nestles in the foothills of the Shawangunk Mountains, one of the small ranges of the Catskills. He became the organist of the First Baptist Church in this village at a salary of fifty cents a week. This first paying job started him off on a career as an organist and choirmaster which helped pay his tuition through Union College and Johns Hopkins Medical School. He received his training in general surgery at the Presbyterian Hospital in New York, and in Urology at the University of Pennsylvania, Duke University and the University of California. At present, Doctor Weyrauch is Clinical Professor of Surgery (Urology) and Chief of the Division of Urology at Stanford University School of Medicine.

The male reproductive organs consist of the *external genitalia*, made up of the penis and scrotal contents, and the *internal genitalia*, comprising the prostate, seminal vesicles and Cowper's glands (Fig. 1). The functions of the male reproductive system are

1. To produce spermatozoa
2. To perform copulation
3. To produce and secrete hormones

The penis, which is primarily composed of erectile bodies, provides a conduit for the urethra and serves the important function of copulation. The testes produce both spermatozoa and hormones. Other genital structures form the efferent tract by which spermatozoa are collected and conveyed to the outside—the epididymides, vasa deferentia and ejaculatory ducts. Thereafter the spermatozoa are conducted through the

urethra, which serves as a channel for both seminal fluid and urine. The prostate gland, the seminal vesicles and Cowper's glands play an accessory role in providing glandular secretions which serve as a vehicle and lubrication for the passage of spermatozoa.

There will be discussion, first, of pathologic conditions affecting the external genitalia, second, of the internal genitalia and, third, of diffuse abnormalities which affect more than one organ of the reproductive system. These last conditions may be confined to the reproductive system or may participate in systemic abnormality.

EXTERNAL GENITALIA

Although the organs of the external genitalia are in close association they constitute three anatomic units. (1) the penis and

Figure 1 Male reproductive system

urethra, (2) the scrotum and scrotal contents and (3) the inguinal lymphatic system.

PENIS AND URETHRA

The penis is primarily a sexual organ, secondarily it encompasses a portion of the urethra. The three erectile tissue components are the two corpora cavernosa situated dorsally and the corpus spongiosum penis

on the ventral surface (Fig. 2). The corpus spongiosum contains the urethra and is capped distally by the glans penis. The corpora are enclosed in fascial sheaths and all in turn are surrounded and bound together by a dense fibrous envelope known as Buck's fascia. This serves as a barrier against extravasation of urine and the spread of infectious processes. The corpora cavernosa are anchored to the ischiopubic rami. Passing

Figure 2. Cross section of penis.

between and below them, the corpus spongiosum surrounds the urethra in its bulbous extent before the urethra enters the external layer of the urogenital diaphragm. The penis is fixed to the pubis at its root by the suspensory ligament. The lax elastic composition of the penile skin permits enormous inflammatory edema and extensive burrowing of subcutaneous blood.

The penis derives a rich blood supply from the internal pudendal arteries. Venous drainage is provided by the dorsal veins of the penis which pass through the prostatic plexuses. This unusually rich vascularity is advantageous in controlling infections and in favoring wound healing. The lymphatic drainage from the penis is to the superficial and subinguinal lymph nodes, that from the glans penis is to the subinguinal and external iliac nodes. The lymphatics from the urethra empty into the hypogastric lymph nodes.

Although the mechanism of erection is poorly understood, it is produced by rapid engorgement of the cavernous bodies by blood through psychic and nervous stimuli. When the blood supply to the penis is impaired or when the nervous supply is damaged the ability to attain erections may be lost.

ANOMALIES

The common anomalies of the penis are phimosis and those in which the urethra is primarily at fault. Anomalies such as absence of the penis, double penis, micropenis, congenital torsion and transposition of the penis and scrotum are rarely encountered in clinical practice. They are likely to be associated with severe abnormalities in other parts of the body which are incompatible with life. Penile anomalies are caused by maldevelopment of the genital tubercle and of those portions of the urogenital sinus involved in the formation of the external genitalia.

Phimosis designates the condition in which the orifice of the prepuce is too small to permit retraction behind the glans penis. It may be either congenital or acquired. Acquired phimosis usually arises from infection and subsequent edema and scarring. Phimosis predisposes to infection of the glans penis and prepuce. In extreme degree it may cause obstruction of the urethra with profound changes in the bladder and the upper urinary tract.

During adult life phimosis impairs the transmission of normal sensation from the nerve endings of the corona of the penis

during coitus. Infection may lead to dyspareunia and difficulty in performing coitus.

Treatment of phimosis consists of circumcision. This operation should be performed during infancy to prevent the described complications. When there is marked infection, preliminary dorsal slit is indicated. At the time of performing circumcision, it is important to release any adhesions between the prepuce and the glans penis and to be certain that the external urethral orifice is of adequate size. If the orifice is too small it should be enlarged by external urethrotomy at the time of circumcision.

Hypospadias is a common deformity of the penis and urethra in which the anterior urethra terminates at some point on the undersurface of the penis, proximal to the normal position at the tip of the glans. Embryologically, hypospadias results from imperfect closure of the urethral groove, the margins of which normally fuse in the midline to form the floor of the urethra. It is a hermaphroditic manifestation in which the urogenital derivatives in the male tend to develop toward the female side.

Depending upon the degree of hypospadias, the types are designated as balanitic or glandular, penile, penoscrotal and perineal (Fig. 3). The fundamental defect is in the urethra and the corpus spongiosum which, excepting in the balanitic type, produces a shortening of the ventral aspect of the penis. This causes a downward curvature of the

Figure 3 Types of hypospadias. a, glandular; b, midpenile; c, perineal; d, sigmoid perineal.

penis which is most marked during erection, known as chordee (Fig. 3d). Deficiency of the prepuce on the ventral aspect causes the dorsal portion to be prominent, giving a hooded appearance (Fig. 3d).

Although balanitic hypospadias is largely asymptomatic the other types lead to difficulty in urination due to the abnormal location of the external urethral orifice and to difficulty in coitus caused by chordee. Since the defect is confined to the anterior urethra there is neither deficiency of the urinary sphincters nor incontinence.

Diagnosis is established by inspection of the external genitalia. It is occasionally difficult to distinguish simple hypospadias from hermaphroditism without biopsy of the gonads. Bilateral cryptorchism may be present and complicate the clinical picture.

The treatment is surgical—to enable the patient to urinate and to copulate in the normal manner. As a general rule, disability is so slight in the balanitic type that treatment is not required. Surgical treatment of the other types consists of correcting the chordee by excision of fibrous tissue and constructing a new urethra by plastic operation. Circumcision should be avoided in hypospadias since the skin of the prepuce often proves useful in surgical correction of the anomaly.

Epispadias is a congenital absence of the upper wall of the urethra at some point proximal to the glans which has a "spade-like" appearance. It is an inevitable counterpart of exstrophy of the urinary bladder in the male, when it occurs alone it may be considered as a mild exstrophy. Although epispadias is much less common than hypospadias it is more disabling. The usual site of the urethral opening is at the abdomino-

Figure 4. Epispadias.

penile junction (Fig. 4). There is commonly an associated defect of the urinary sphincters which causes urinary incontinence.

Treatment is surgical by plastic repair of the penis and urethra—to correct urinary incontinence and the inability to copulate.

TRAUMA

With the exception of paraphimosis, injuries of the penis are extremely rare. Self-mutilation, such as contusion from pressing or pinching during masturbation, or strangulation, from forcing the organ into the neck of a bottle or other firm constricting ring, accounts for many. Incised or gunshot wounds may lead to profuse hemorrhage. A severely injured penis will usually heal promptly if immediately sutured. When the penile blood supply has been completely severed the organ must be amputated.

Paraphimosis is a condition in which the prepuce when once retracted behind the

Figure 5. Methods of manual reduction of paraphimosis.

glans penis cannot be replaced in its normal position. It is frequent in the uncircumcised, particularly during infancy. Infection of the prepuce predisposes to development of this abnormality. Constricting rings of skin may lead to vascular occlusion and superficial thrombosis or gangrene. The glans penis is not affected because of its independent blood supply through the corpus spongiosum.

Paraphimosis can usually be reduced manually (Fig. 5), hyaluronidase being first injected into the subcutaneous tissues. In chronic cases, and particularly when infection is marked, dorsal slit of the prepuce may be required. Circumcision should be carried out when the inflammatory reaction has subsided. Of chief importance is prophylaxis, performing circumcision when the prepuce is tight or redundant and cautioning mothers in the care of infants to avoid leaving the prepuce in the unretracted position.

Dislocation of the Penis results from severe trauma in the erectile state. There is usually associated rupture of the urethra. The penis is inverted and disappears into the scrotum or the adjacent tissues of the inguinal or suprapubic region. There may be considerable swelling from subcutaneous hemorrhage and urinary extravasation. An immediate attempt should be made to restore the penis to its normal position and urinary diversion should be performed.

INFECTIONS

Aside from the venereal infections, which rarely constitute a surgical problem, the penis is relatively immune to infection. The abundant blood supply is helpful in combating pyogenic infections such as cellulitis, erysipelas and furuncles. Nonvenereal infections of the urethra are usually secondary to obstruction or urethral instrumentation.

Posthitis, Balanitis, Balanoposthitis. Balanitis is inflammation of the glans penis, posthitis of the prepuce, the combined inflammatory lesion is known as balanoposthitis. These inflammations are usually caused by retention of secretions and bacteria beneath a redundant prepuce.

Local signs and symptoms vary according to the severity and etiology of the infection. The patient usually complains of local itching, burning and pain and in the more virulent infections a purulent discharge is present. The presence of a discharge may cause confusion in making a differential diagnosis between urethritis and balanoposthitis.

When the infection is not a complication of gonococcal urethritis or other specific disease the treatment is routine cleansing and drying of the involved surfaces. In acute infection the type of bacteria is determined by smear and culture and appropriate antibacterial agents are administered. In infections that resist treatment a dorsal slit is performed to facilitate drainage. When the acute process has receded circumcision is usually indicated to prevent recurrence.

Herpes Progenitalis is a common lesion of the penis caused by a virus. It is manifest by groups of vesicles on the surface of the glans or prepuce along the distribution of the dorsal penile nerve. The lesions are similar to herpes elsewhere. They appear as small, superficial red spots which become vesiculated and rupture, leaving superficial ulceration. Mild itching and burning are the chief symptoms. Local cleansing and the application of a dusting powder, such as zinc stearate, are helpful. When the prepuce is redundant, circumcision is indicated for recurrent herpes.

Condylomata Acuminata, usually known as venereal warts, are soft, painless, cauliflower-like growths which appear on the prepuce, glans penis and within the adjacent urethra. The lesion is aggravated by secretions and dampness. A redundant prepuce is usually the chief predisposing factor. Despite the common name, venereal warts are not contracted sexually. Like herpes, they are caused by a virus. The lesions are usually numerous and vary in size from a few millimeters to a centimeter in diameter. Occasionally they attain tremendous size.

In treatment, cleanliness and dryness are the important factors in prophylaxis and in preventing recurrence. For this reason, circumcision is helpful. Once developed, the lesions can usually be eradicated by local application of 25 per cent podophyllin in castor oil. Care must be exercised to avoid application of the drug to uninvolved portions of the skin and mucous membrane. In resistant cases, electrofulguration proves effective.

Cavernositis is an infection of the erectile bodies of the penis, usually secondary to acute gonorrhea or acute nonspecific urethritis. It may complicate trauma, especially with urinary extravasation, and occurs in some systemic diseases, such as leukemia.

The condition is evident as a tender, indurated area in one of the cavernous bodies.

The urethra may be compressed, causing difficult urination. Occasionally cavernositis leads to priapism. Like periurethral abscess, a cavernous abscess may rupture into the urethra. Treatment consists of specific antimicrobial therapy and incision and drainage in resistant cases.

NEOPLASMS

Carcinoma of the penis, the usual malignant lesion, comprises only 1 per cent of all cancers of the urogenital tract. Such common skin neoplasms as nevi, hemangioma and papilloma offer little clinical difficulty since local excision provides both the diagnosis and definitive treatment.

Carcinoma of the Penis usually develops in men over fifty years of age. Circumcision in infancy grants almost complete immunity. Circumcision later in life is valuable but decreasingly so as the patient becomes older. These considerations suggest that the exciting cause operates over a period of many years, apparently contributed to by preputial secretion (smegma) and/or chronic bacterial irritation.

Most of these carcinomas are composed of squamous cells. They may be divided into the verrucous and ulcerated types. The papillomatous may originate from condylomata acuminata and tend to grow quite large although they are less invasive and are of a lower grade of malignancy than flat, ulcerative types. Metastasis is chiefly by way of the lymphatics so that the inguinal and femoral lymph nodes must be carefully examined in every suspected case. However, it must be determined by biopsy whether enlargement of these nodes is caused by secondary infection or carcinomatous invasion. Distant metastasis from carcinoma of the penis occurs late, if at all. Since a portion of the lymphatic drainage of the penis extends directly to the pelvic and iliac lymph nodes, these nodes may become involved without invasion of the superficial inguinal lymph nodes.

Symptoms consist of the presence of a painless, slow-growing lesion, most frequent on the glans penis, which may be obscured by a redundant prepuce. Persistent ulceration and the presence of a discharge are common complaints—"a sore which does not heal."

Differential diagnosis must be made with ulcerative lesions of the penis such as chancre and chancroid. Carcinoma is not excluded by a positive serologic test for syphilis. Diagnosis is established by biopsy

With the use of local anesthesia, a small wedge of tissue is removed from non-necrotic tissue at the edge of the ulcer.

In the treatment of carcinoma of the penis surgical therapy remains the method of choice. There is still disagreement as to the most appropriate type of operation; as to whether amputation of the penis 2 cm. proximal to all visible and palpable evidence of the neoplasm suffices or whether this should be combined with extirpation of the inguinal, femoral and pelvic lymph nodes. Radiation therapy, previously employed in treatment, has proved ineffectual and has been largely abandoned.

Carcinoma of the Male Urethra is a rare form of neoplasm, usually of the epidermoid type. It leads to slowing of the urinary stream, hematuria and a urethral discharge. Differentiation from urethral stricture is established by biopsy. Treatment consists of radical surgical extirpation.

SPECIAL DISEASES

In addition to conditions of known etiology there are some penile lesions of idiopathic or protean manifestations.

Plastic Induration of the Penis (Peyronie's Disease) is a common lesion of the fibrous coverings of the corpora cavernosa, usually involving the dorsal aspect and intercavernous septum of these bodies. It appears as a painless plaque of fibrotic tissue similar to keloid formation and to Dupuytren's contracture of the volar tendons of the hand. The incidental finding of a firm area in the penis may call attention to the lesion. As it progresses the fibrotic area limits erection. The penis remains bent in the direction of the involved area. This leads to difficult coitus and sometimes precludes penetration; erection may be accompanied by pain. In most instances the deformity progresses slowly and is subject to long periods of remission regardless of whether or not treatment is instituted. Spontaneous regression occasionally occurs.

Diagnosis is established by palpation of the shaft of the penis. This reveals a well-defined plaque of firm tissue, usually located in the midline of the dorsum and near the base of the organ. Occasionally it is placed distally or laterally or deep between the corpora cavernosa. Occasionally x-rays reveal areas of calcification in the area of involvement.

Numerous forms of treatment have been advocated and their multiplicity bears evidence as to the ineffectiveness of them all.

Of reputed value are x-ray or radium, vitamin E, ultrasonic wave therapy and injection of the fibrotic plaque with hydrocortisone. Surgical extirpation of the plaque is usually unsuccessful since excision tends to increase rather than to eradicate the deformity. Although in most cases the etiology is unknown, in some instances Peyronie's disease arises as a sequel of trauma.

Priapism is a rare affliction manifest by prolonged painful erection of the penis, unaccompanied by sexual desire. In most instances the etiology is unknown. Sometimes there are specific causes such as invasion of the base of the penis by carcinoma of the prostate, penis or urethra, trauma to the corpora or some neurologic disorder, such as injury to the spinal cord. Spontaneous detumescence may occur.

Treatment is notably ineffective. In the early stages of the condition the use of Dicumarol or heparin may be valuable in preventing thrombosis. Aspiration of the cavernous sinuses with a large bore needle or open drainage through incision has been employed with questionable results. Under spinal anesthesia manual expression of thickened blood may provide temporary relief. In a large proportion of prolonged cases, priapism is followed by the loss of power of erection.

SCROTUM

The scrotal sac encloses the testes, epididymides and structures of the spermatic cords. Under the corrugated skin lie the dartos fibers, within this layer are three fascial layers derived from the abdominal wall during testicular descent. The scrotum is divided into two compartments by a septum of connective tissue. It not only supports the testicles but, by relaxation or contraction of the dartos, helps to regulate their environmental temperature. The arteries arise from the femoral, internal pudendal and inferior epigastric arteries. The veins are paired with the arteries. The lymphatics drain into the superficial inguinal and sub-inguinal lymph nodes.

The diagnosis of most scrotal masses can be made by careful palpation and identification of each structure, combined with transillumination, and occasionally by radiography. When doubt remains, exploration of the scrotum may be simply and safely performed.

ANOMALIES

Anomalies of the scrotum are usually associated with anomalies in other parts of

the reproductive system. The most common are a bilobate scrotum resulting from arrest of fetal development and failure of union of the lateral halves along the line of the median raphe. This results in the formation of a separate pouch for each testicle, frequently associated with perineal hypospadias. When there is congenital absence of the testicle or cryptorchism, the affected side of the scrotum fails to develop.

TRAUMA

Although scrotal injuries are few, trauma is occasionally sustained by kicks, blows or gunshot wounds. In any penetrating injury the chief concern is whether there has been damage to the scrotal contents and whether any foreign material has been introduced. Such wounds should be promptly debrided and tetanus antitoxin administered. As a general rule, a compression bandage will check mild hemorrhage, but arterial bleeders require ligation and unless this is promptly executed a large scrotal hematoma will develop. The scrotal skin has a large capacity for regeneration and its loss does not usually require skin grafting, although in reconstruction of the scrotum, the testicles may be initially left in a bizarre position. The presence of urinary extravasation, as from a coincident rupture of the urethra, demands definitive treatment. Serious infection may ensue unless the urine is diverted, proper drainage of the involved tissues instituted and appropriate antimicrobial agents administered.

INFECTIONS

Most infections of the scrotum are secondary to infection of the testicle, urethra or rectum or to urinary extravasation. Scrotal cellulitis and furunculosis are similar to these infections elsewhere on the skin surface.

SPECIAL DISEASES OF SCROTUM

Scrotal Edema. Because of the laxity of the scrotal skin and subcutaneous tissues, edema may progress to startling dimensions. The penis may be similarly involved and so dislocated by invagination as to cause interference with urination. If the urine is discharged over the scrotum, the skin becomes macerated, predisposing to infection and ulceration. Scrotal edema is frequently associated with cardiac or renal disease, blood dyscrasia or abdominal neoplasms which interfere with venous and lymphatic return. On the other hand, it may be secondary to infection of the testicle.

structure. Treatment of scrotal edema consists of a high scrotal support while definitive treatment is being applied to the primary cause. In the absence of complicating infection, surgical drainage is unnecessary and contraindicated because of the danger of producing cellulitis and bacteremia.

Elephantiasis is a chronic disease caused by interruption of the lymphatic drainage of the scrotum, leading to hypertrophy of the skin and edema of the subcutaneous tissue with tremendous enlargement of the affected areas. There are two forms: the nonfilarial and the filarial, which is limited to tropical and semitropical regions. Non-parasitic elephantiasis may result from excision or postoperative sclerosis of the inguinal lymph nodes into which the scrotal lymphatics drain. Parasitic elephantiasis is common in many Asian countries, especially India. The condition results from infection with the nematode *Wuchereria bancrofti*, an organism which utilizes two hosts, man and certain mosquitoes, to complete its life cycle. Filaria are blood borne to the lymphatics where they interrupt drainage of the regional lymph nodes.

In elephantiasis the scrotum may enlarge to such an extent as to reach the level of the knees or even touch the ground as the patient walks. The tissues have a brawny hardness attributable to fibrous infiltration and hyperplasia of the cutaneous tissues which become coarse in texture. Since the cutaneous blood supply is preserved gangrene seldom develops.

In the differential diagnosis it is important to recognize that pyogenic inflammation of the scrotum and urinary extravasation may simulate elephantiasis.

Aside from treating the primary disease if it is recognizable, treatment of elephantiasis consists of plastic excision of the scrotum, preserving the testicles, which are unaffected by the lesion.

Scrotal Gangrene is caused by interference with the cutaneous blood supply of the scrotum. It may result from any one of several causes. (1) infected wounds, (2) chemothermal or mechanical trauma without infection, (3) any condition such as cardiovascular disease leading to scrotal edema, (4) systemic diseases such as diabetes which predispose to infection, (5) urinary extravasation with secondary infection.

Diagnosis is made by inspection. Gangrenous areas of skin show a purple, dark green or black discoloration. Treatment consists of appropriate antimicrobial therapy

when there is complicating infection, together with excision of gangrenous tissues; incision and drainage prove inadequate.

NEOPLASMS

Neoplasms of the scrotum are extremely rare. Although a few benign tumors such as polyps, fibromas, adenomas, lipomas and hemangiomas have been reported, a malignant skin neoplasm, *chumney-sweeps' cancer* holds chief clinical interest. It is occupational, being associated with prolonged exposure to bacterial or chemical products which contain carcinogens. Some sensitivity of the skin in persons of fair complexion may be a possible contributing factor. Pathologically this carcinoma has many of the characteristics of carcinoma of the penis. Treatment consists of wide excision, with removal of one or both testicles in advanced stages of neoplasm. As in carcinoma of the penis, radiation therapy is ineffective.

TESTES

The testes are two ovoid, tunic-covered organs, suspended in the scrotum by the spermatic cord. At the upper pole of each is a small pedunculated body, the appendix testis. The testes are enclosed in a dense fibrous capsule, the tunica albuginea, which forms into fibrous septa that penetrate the glandular structure, converging at the hilum. Between the septa are the spermatic tubules which produce and conduct spermatozoa to the vasa efferentia and thence to the epididymis (Fig. 1). Within the framework of the septa are the interstitial cells of Leydig. These cells elaborate an androgenic hormone which influences sexual development and activity. Posterolaterally the testes are attached to the epididymides. Elsewhere they are firmly covered by the tunica albuginea which forms the visceral layer of their investment by the tunica vaginalis testis.

The blood supply to the testis is closely associated with that to the kidney because of a common embryonal origin of the two organs. The arteries to the testis, the internal spermatic, arise from the aorta below the renal artery. The venous return is through the pampiniform plexus of the spermatic cord to the spermatic vein. On the right the spermatic vein enters the vena cava below the right renal vein, on the left it empties into the renal vein. The longer blood column on the left with its increased hydrostatic pressure may be a participating cause of varicocele.

Figure 6 Testicular anomalies

The lymphatic drainage from the testis is to the common iliac and lumbar lymph nodes, which in turn communicate with the mediastinal and supraclavicular chains, an anatomic arrangement intimately concerned with the spread of carcinoma of the testis.

The testicular nerves are from the aortic and renal plexuses by way of the spermatic cord. Because of the intimate connection of the spermatic, aortic and solar plexuses, abdominal pain may be produced by trauma to or acute infection of the testicle.

ANOMALIES

Of the congenital anomalies of the testicle, anomalous location is the most frequent, cryptorchism much more so than ectopy. Absence of one or both testes or their duplication is a rare anomaly. Hypoplasia is unusual in the normally descended organ. The possible variations are listed in Figure 6.

Cryptorchism, or undescended testicle, is the most common of all anomalies of the male reproductive system. The term connotes the existence of a hidden testicle. The location may be any place along the course of normal descent—intra-abdominal, inguinal or prepubic (Fig. 7). In many animals the testes do not descend normally until after birth. In some they descend only during the mating season, in others they remain in the abdominal cavity at all times. In man the testes are usually located in the scrotum at birth, but in some instances descent is delayed and may occur at any time up to puberty. Occasionally the testes migrate, being in the scrotum at some times and absent from it at others, being retracted during cold or nervous stimulation by an active cremasteric reflex.

The cause of cryptorchism is obscure. In a few cases (less than 15 per cent) it is the result of endocrine dysfunction, such as

hypopituitarism. At one time mechanical factors were considered to be the cause; in recent years more emphasis is being given to an incapacity of the testis to respond to normal stimuli. The disclosures of testicular biopsy indicate that there is inherent testicular deficiency which may be the cause of arrested descent. Biopsy has shown that in undescended testes there is failure of tubular development which normally takes place after the age of ten years. This failure is observed even after orchiopexy.

The chief diagnostic signs of cryptorchism are absence of the testicle from the scrotum and underdevelopment of the empty scrotal sac. If these findings are complemented by the palpation of a testicle in the inguinal or prepubic region, the diagnosis is established. However, if the testicle is in the abdomen and cannot be palpated, cryptorchism must be differentiated from agenesis. As the testicle is palpated in the inguinal canal or abdomen, the patient may feel the typical sensation of the testicle being compressed. The examiner should have warm hands, make certain that the patient is fully relaxed and conduct the examination as gently as possible. When there is doubt, the examination should be conducted on more than one occasion. The differential diagnosis must exclude migrating testicle, the condition with which it is most likely to be confused. When the patient is relaxed, even though a migrating testicle has been retracted into the inguinal canal, it can usually be "milked"

into the scrotum—a maneuver which cannot be accomplished with undescended testis.

In cryptorchism, androgens are secreted, but sperms are not produced. As a result, the adult with bilateral cryptorchism yields an azoospermatic ejaculate although he has normal libido and potentia. Most adults with unilateral cryptorchism are normally fertile.

Pain in an undescended testicle usually signals the onset of some complication such as inguinal hernia, torsion of the spermatic cord, inflammation or neoplasm. The inguinal testis is relatively fixed and is more easily injured than the mobile scrotal testis.

In all types of undescended testis the incidence of malignancy is about thirty-three times more than for the scrotal testis, the intra-abdominal testis being four times more vulnerable than the inguinal one. Orchiopexy does not lessen the incidence of neoplasm.

Since the *processus vaginalis* precedes the testis in its descent, it may reach the scrotum independently and remain patent, even when the testis remains in the abdominal cavity. The condition must be recognized at operation so that the sac can be obliterated and the danger of development of a hernia allayed.

For the treatment of cryptorchism, chorionic gonadotropin may be used in an attempt to produce descent. Small doses of testosterone propionate may also be given, either alone or in combination with chorionic gonadotropin. If there is hypothyroidism, thyroid extract should be given in doses

ECTOPIC

CRYPTORCHID

Figure 7. Anomalous positions of testicle.

commensurate with the degree. In assessing the value of hormonal therapy, it must be recognized that normal descent may take place up to the time of puberty.

If descent fails to occur spontaneously or following hormonal therapy, three alternatives are possible: continued observation, orchiopexy or orchiectomy. The stated objectives of treatment are to produce fertility, eliminate a potential focus of malignant degeneration, correct an associated inguinal hernia and for cosmetic effect. Unfortunately operation rarely, if ever, restores fertility and apparently it does not reduce the incidence of carcinoma. One questionable reputed advantage is that after orchiopexy, the testis is in a better location for observation to detect the earliest changes of malignancy.

In attempting to promote spermatogenesis, some observers advise that orchiopexy be performed before the patient reaches the age of five years, others think that ten years is sufficiently early. There is general agreement that the operation should be performed before the patient reaches puberty.

Orchiectomy is indicated at the time of operation when it is found that it is not possible to bring an undescended testis into the scrotum, providing the opposite testis is present and normally located in the scrotum.

Ectopic Testis. In rare instances the testicle lies outside its line of normal descent. Vicarious excursion usually takes place after the testicle has emerged from the inguinal canal. The most common site is in the superficial inguinal region, less common are the subcutaneous tissues of the perineal and femoral regions. The penile position is extremely rare (Fig. 7).

Diagnosis is made by palpating the ectopic testis in its anomalous position. Treatment is surgical, placing the organ in the scrotum.

In extremely rare cases the testis is located in the true pelvis, having strayed from the normal path of descent before entering the inguinal canal. This condition usually is discovered only at necropsy.

TRAUMA

Because of their mobility and the protection afforded by the pelvic arch, the testes are seldom injured. Occasionally straddle or perforating injuries lead to contusion, laceration, puncture or dislocation. Extravasation of blood may cause infarction and atrophy of the testis. In some Oriental countries eunuchs are prepared for the harem by prolonged compression of the testicles with

resultant atrophy. Trauma to the testicle, even mild, may cause excruciating pain referred to the abdomen, associated with nausea and vomiting, faintness and shock. On rare occasions, a severe blow to the scrotum dislocates the testicle into the abdomen or the subcutaneous tissues of the penis or perineum. Diagnosis is made on the basis of the history and local signs of injury. Operation is indicated for evacuation of blood and to replace the dislocated organ. Penetrating wounds require suture of the tunica albuginea and scrotal lacerations.

Torsion of the appendix testis is primarily a prepubertal condition. The cause is unknown. It leads to exquisite testicular pain and tenderness on palpation. In the early stages, the diagnosis can sometimes be established by palpation of the tiny undurated body, later, with edema, diagnosis may not be made until operation. The condition is frequently mistaken for torsion of the spermatic cord or acute epididymitis. Treatment is operative—excision of the affected appendix.

INFECTIONS

In contrast to the epididymis, which is usually invaded by pyogenic bacteria, the testis is usually invaded by viruses. This exemplifies Cabot's doctrine of the prepared soil. Much like many vegetables which require a certain soil for growth, bacteria and viruses require a particular cellular environment. Bacterial orchitis almost always represents an extension from infection of the epididymides. Only in rare instances, as during bacteremia, do metastatic foci develop in the testis without first infecting the epididymis.

Of the infections, mumps orchitis is most frequent. It rarely develops before puberty, but complicates epidemic parotitis in one-fifth of male patients beyond the age of puberty. It begins four to six days after the onset of parotitis, in most instances is unilateral and causes fever.

Physical examination reveals an enlarged, tender testis. Differentiation is made from acute epididymitis by a lack of induration in the epididymis and a sharp sulcus dividing the testis from an inflamed epididymis. The testicle is not elevated, as it is in torsion of the spermatic cord. Clinical evidence of parotitis or of systemic viral infection aids the diagnosis. Less common than mumps orchitis is orchitis complicating smallpox, varicella, measles, influenza and dengue fever.

Prophylaxis consists of keeping patients with viral infections in bed during the acute illness. Treatment is symptomatic: elevation of the scrotum and either warm or cold applications to relieve pain. Surgical incision of the tunica albuginea has been advised to prevent atrophy, particularly in bilateral lesions. Estrogens and cortisone have been used with some favorable results.

Although the testis retains its hormonal function, the testis usually atrophies and spermatogenesis is usually terminated by viral orchitis.

Tuberculous orchitis is usually secondary to tuberculous epididymitis. Syphilitic orchitis has been rendered a medical curiosity by the modern treatment of syphilis in the countries where this is possible.

NEOPLASMS

Fortunately tumors of the testis are uncommon, for they are one of the most dangerous forms of malignancy in the male. The onset is insidious, growth is rapid and early metastasis is frequent. Whereas nearly all tumors of the epididymis are benign, practically all tumors of the testis are malignant. Testicular neoplasms comprise from 1 to 2 per cent of all malignant tumors and account for about 3 per cent of the malignant conditions of the male urogenital tract. Although their age range is from infancy to old age, most are found in patients during the ages of greatest sexual activity, twenty to forty years.

Testicular tumors arise from totipotent sex cells capable of reproducing any of the tissue derived from the three primary germ layers. Although indicted by many as a cause, injury has nothing to do with initiating a testicular neoplasm. It may call attention to an existing tumor. The cryptorchid testis is more likely to be the site of a neoplasm than is a normally descended gonad. If the patient has bilateral cryptorchid testes and carcinoma in one, there is such a high incidence of carcinoma in the opposite testis (about 25 per cent) that bilateral orchiectomy is justified.

Testicular tumors may be placed in any one of four groups: (1) seminomas, (2) carcinomas, (3) teratomas and (4) interstitial cell tumors.

Seminoma is more common and less malignant than the other forms, is more radio-sensitive, has a lower incidence of metastasis and a lower mortality rate. Tumors with a carcinoma cellular pattern may be either adenocarcinoma or chorioepithelioma. They

tend to invade near-by structures and to metastasize early. Teratomas are bizarre neoplasms which contain differentiated adult structures such as bone, cartilage, brain, skin and organs resembling teeth and hair. Interstitial cell tumors comprise less than 1 per cent of testicular tumors. They arise from Leydig's cells to which they are cytologically similar. In general, they cause masculinization and most are benign.

Early diagnosis of testicular neoplasms is difficult because of a lack of symptoms. Despite the relatively exposed position of the testicle, patients may be unaware of the tumor for a long time. The initial symptom is usually a painless swelling in the scrotum. With further growth, a dull, dragging sensation develops. In the later stages, an abdominal mass, representing metastatic lesions in the lymph nodes, may be noted. Gynecomastia has occurred in patients unaware of any testicular swelling, as a result of hormonal secretion by the tumor.

Not infrequently, the first manifestation of a testicular neoplasm arises from a metastatic lesion, such as hemoptysis from pulmonary metastasis. Dissemination is commonly by way of lymph channels, although the blood also may be responsible, especially in the more malignant types (Fig. 8). Metastatic lesions tend to advance rapidly.

Figure 8. Metastatic areas, carcinoma of testis.

Sometimes the cellular pattern of the metastatic lesion differs from that of the primary neoplasm. Since lymphatic drainage from the testicle is periaortic, rather than to the inguinal lymph nodes, extension is to the peri-iliac and thence to the periaortic lymphatics. The metastasis tends to skip glands and to cross to the opposite side. Involvement of the glands surrounding the renal pedicle causes displacement of the kidney and upper portion of the ureter. Spread may be as high as the mediastinum and supraclavicular lymph chains (Virchow's node). The thoracic duct and its surrounding lymphatics are frequently involved. Blood-borne metastasis is commonly to the lungs and the liver.

The size of the primary tumor bears no close correlation with the time of onset or multiplicity of metastatic lesions. Many neoplasms 1 cm. or less in diameter may spread to other organs. In some patients the primary growth is discovered only after metastatic lesions appear, others come to necropsy before the true nature of the metastasis becomes known.

In examination of the external genitalia, it is important to determine whether any scrotal mass lies in the testis or in the epididymis since enlargement of the epididymis is usually benign. The typical characteristic of a testicular neoplasm is a stony-hard mass of increased weight confluent with the structure of the testis. Although tumors are rarely painful, the fact that tenderness is present does not rule out a neoplasm. Occasionally a tumor coexists with epididymitis. Increased vascularity of the scrotum and invasion of the spermatic cord are late signs. With extensive lymphatic involvement there may be edema of the lower extremities.

Auxiliary diagnostic studies are x-rays of the chest and intravenous urograms. The former discloses pulmonary metastasis, the latter, displacement of the kidney or ureter by enlarged periaortic lymph nodes (Fig. 8). The urine should be examined for chorionic gonadotropin since this hormone is excreted in many testicular tumors. It is most marked in the carcinoma group, less common in seminomas; it usually does not occur in the teratoid group. Since hormonal tests may be negative in all types of tumor, their value in this diagnosis is limited.

Testicular neoplasms have been mistaken for hydrocele, spermatocele, hematocele, epididymitis, torsion of the spermatic cord and orchitis. If hydrocele is present, aspira-

tion of the fluid permits better examination of the testis. Whenever the nature of an intrascrotal enlargement is doubtful, operation should be performed.

The treatment of malignant tumors of the testis is orchietomy supplemented by radiation of the primary lymph zone, providing the tumor is radiosensitive. Radiosensitivity is not always easy to determine because the metastatic lesions may show a different pattern than the primary tumor. Seminomas are the most radiosensitive; chorioepithelioma and carcinoma are more resistant; the lethal dose for mature teratoma cannot be reached with safety (Fig. 9). In treating the latter types, excision of the regional lymphatics, including those about the renal pedicle, is advised by some surgeons. Orchietomy for neoplasm consists of ligation of the spermatic cord at the uppermost extent of the inguinal canal and removal of the intact cord and scrotal contents. In gland dissection, lymph nodes on both sides of the aorta should be removed because of the tendency to cross-metastasis.

Prognosis depends on

of the tumor and its extent. It depends well to orchietomy and deep x-ray therapy. Embryonal carcinomas and teratocarcinomas have a higher mortality rate and chorioepitheliomas are the most malignant. As a general rule, decrease in the chorionic gonadotropic hormone indicates removal or regression of chorionic tumor tissue; increase means spread of the disease. However, after operation, negative hormonal tests are occasionally noted in the presence of widespread metastasis.

EPIDIDYMIDES

The epididymides are a pair of crescentic structures composed of tremendously coiled ducts. They lie posterolateral to the testes (Fig. 1) to which the rete testis provides

communication. The appendix epididymis is a small, pedunculated body attached to the upper pole. The elongated upper end of each epididymis, termed the globus major, is flattened against the testis; the body comprises the midportion; the lower end, the globus minor, gives rise to the vas deferens. An infection in the globus minor may seal off the spermatic ducts, causing sterility of the involved testis.

In addition to providing conduits, the epididymides contribute to the maturation of spermatozoa. Spermatozoa first become motile after passage through the head of the epididymis. However, the fertilizing capacity of spermatozoa recovered from the head is low; those recovered from the body or tail are more fertile.

The arterial supply to the epididymis comes from the internal spermatic artery and the artery of the vas deferens. The venous drainage is through the pampiniform plexus into the spermatic vein. The lymphatics drain into the external iliac and hypogastric lymph nodes.

ANOMALIES

The most usual anomaly is in position, the epididymis lying anterior rather than posterior to the testis. Lack of fusion between the epididymis and testis has been reported. Congenital absence of the epididymis is extremely rare.

TRAUMA

Injuries of the epididymis accompany trauma to the testis. Differential diagnosis is made at operation. Clinical recognition and treatment are similar to those of injury of the testis.

INFECTION

Epididymitis is the most common disease of the scrotal contents and is relatively frequent in males of all ages. It may be non-specific, gonococcal or tuberculous.

Nonspecific Epididymitis is commonly a sequel to prostatitis, the usual pathway of invasion being the vas deferens. Acute nonspecific epididymitis, spread by the blood from a distant focus, is rare. Any of the bacteria which invade the urinary tract may cause epididymitis.

Acute epididymitis is a fulminating process manifest by diffuse cellulitis with swelling and edema. The inflammation usually arises in the tail of the epididymis and thereafter involves the entire organ. The chief symptoms are pain and swelling. There

is frequently a prodromal ache in the inguinal region or discomfort along the spermatic cord. Systemic symptoms such as chills, fever, headache, nausea and vomiting occur with more virulent infection.

Diagnosis is established by gently palpating the enlarged, exquisitely tender epididymis. An important physical sign is detection of the sulcus between the enlarged epididymis and the testis. Involvement of the vas deferens by coincident vasitis contributes evidence of epididymitis. The spermatic cord may be thickened by edema. Hydrocele may develop secondary to infection. Specific diagnosis is made by identifying the bacteria present in any urethral discharge or in the urine. Digital rectal examination should be performed to learn whether there is coincident prostatitis or seminal vesiculitis. Palpation must be gentle to avoid producing bacteremia and dissemination of the genital infection.

In making a differential diagnosis, it is important to rule out torsion of the spermatic cord or of the testicular appendages. Elevation of the scrotum usually relieves the pain of epididymitis but not of torsion. In torsion of the spermatic cord, the testicle lies high in the scrotum. When examination is unsatisfactory because of exquisite tenderness, injection of the spermatic cord with 1 per cent Xylocaine will facilitate the procedure. The physical findings in trauma to the testicle may simulate those of acute epididymitis, but the history of injury and the absence of a urethral discharge or pyuria aid in differentiation. When doubt exists, diagnosis is established by operation.

Treatment consists of prompt administration of the appropriate antimicrobial agent and elevation and immobilization of the scrotum. The patient with acute epididymitis should be kept in bed until any fever subsides, in order to help limit spread of the infection. Indications for epididymotomy are a high unremitting fever, excruciating pain and bilateral epididymitis. It is believed that by performance of epididymotomy, resolution is more likely to take place without scar tissue formation and resulting sterility.

Epididymitis secondary to operation on the prostate has been largely eliminated by performing bilateral vasectomy before or at the time of prostatectomy.

Chronic epididymitis is usually a sequel of acute epididymitis but at times arises insidiously as a subacute process giving rise to little pain or discomfort. In chronic infection, the organ is thickened and slightly

enlarged. It may or may not be tender. Differential diagnosis must be made from tumor of the testis by carefully palpating the testicle to be certain that any induration is confined to the epididymis. Since the two may occur together, whenever there is a coincident mass in the testis operation is indicated to learn the true state of affairs. Nonspecific epididymitis is treated by eliminating the source of the infection, usually a prostatic infection. In such cases, vasectomy usually prevents acute exacerbations. If chronic epididymitis causes persistent pain, epididymectomy is indicated. Administration of antimicrobial agents is usually fruitless. Epididymovasostomy, with anastomosis of the vas to the upper part of the epididymis, may restore fertility, if fibrosis is limited to the globus minor.

Gonococcal Epididymitis used to be a common complication of gonococcal urethritis. With the reduced incidence of gonorrhea, brought about by modern antimicrobial therapy, it is now rare. The infection nearly always results from improper treatment of anterior gonococcal urethritis, allowing extension to the posterior urethra and thence down the vas deferens to the epididymis. The lesions and symptoms of both acute and chronic gonococcal epididymitis are similar to those of nonspecific epididymitis with one significant difference. With resolution of the acute inflammation, the tissues affected by the gonococcal process are more likely to be replaced by scar tissue which occludes the epididymal tubules. If this is bilateral, sterility results. Scar tissue, easily palpable, causes permanent induration in the globus minor of the epididymis.

Tuberculous Epididymitis. The epididymis is one of the common sites of urogenital tuberculosis. The incidence of epididymitis is highest in patients from twenty to forty-five years old and is usually secondary to tuberculous prostatitis or seminal vesiculitis. Extension is usually by way of the vas deferens; less commonly, it spreads by means of the blood from a distant focus, for example in the lungs or kidneys. Tuberculous epididymitis usually presents as an indurated enlargement of the organ. Upon palpation, nodularity and thickening are noted, a process which may involve the vas deferens. There is usually little tenderness, despite considerable involvement of the epididymis. In advanced cases, caseation takes place. The process may then involve the subcutaneous tissues and the skin, causing edema, ulceration and fistula formation. The

testis is invaded late, being relatively immune to the tubercle bacillus. Secondary infection may take place, giving rise to all the manifestations of acute nonspecific epididymitis.

With respect to diagnosis, the history and presence of tuberculosis elsewhere, particularly in the urogenital tract, should suggest tuberculosis. Proof is obtained by isolating tubercle bacilli in the urine or discharge from a sinus and with surgical exploration by microscopic examination of the tissue. In chronic cases, calcification may be noted on x-ray of the scrotum. Differential diagnosis must be made between nonspecific epididymitis, coccidioidomycosis and tumor of the testis or epididymis.

If the lesion is not far advanced, chemotherapy and general measures directed to tuberculosis elsewhere in the body may suffice. If there is caseation and particularly if there is scrotal fistula, operation is indicated, excising the vas deferens, epididymis and involved tissues of the scrotum.

NEOPLASMS

Tumors of the epididymis are extremely rare and, in contrast to testicular neoplasms, most are benign. These include angioma, myoma, leiomyoma and dermoid cyst. Examination shows a mass in the epididymis which does not transilluminate. Tumors may be mistaken for tuberculous epididymitis. The precise diagnosis will seldom be made without microscopic examination of tissue. Malignant neoplasms of the epididymis are chiefly adenocarcinoma, although occasionally a sarcoma is present. Since these tumors grow rapidly and frequently invade the testis, they may be mistaken for testicular neoplasm. Treatment is similar to that for tumor of the testis, i.e., removal of the testicle followed by radiation. The prognosis is usually poor.

MISCELLANEOUS CONDITIONS

A spermatocele consists of a diverticulum of the epididymis (Fig 10a). It is a single or multilocular cystic structure communicating with the vasa efferentia. It contains a cloudy fluid usually found to be teeming with motile spermatozoa when examined microscopically. The typical spermatocele is a small, cystic, nontender, spherical mass which transilluminates, usually attached to the upper pole of the epididymis. Usually the condition is asymptomatic and discovered as an incidental finding on examination of the scrotal contents. Treatment is not

indicated unless the spermatocele attains considerable size and causes pain, in which case excision is indicated. The differential diagnosis lies chiefly between various types of hydrocele or the rare epididymal neoplasm. The cystic consistency of the mass and the characteristic of transillumination establish the diagnosis. Aspiration of the spermatocele yields fluid containing spermatozoa. However, this procedure is followed by recurrence and there is the hazard of producing hemorrhage and infection.

TUNICA VAGINALIS TESTIS

The tunica vaginalis testis is a pouch formed by two layers of connective tissue. It is a remnant of the peritoneal prolongation into the scrotum. The visceral layer covers most of the epididymis and is firmly attached to the tunica albuginea testis, the parietal layer forms the outer covering, a secretion from the cells of the endothelial lining lubricates the space between the two. When excess fluid accumulates, a hydrocele is produced. Although the processus vaginalis is usually open at birth, it is closed within the first month in most infants.

ANOMALIES

When the processus vaginalis fails to close and remains patent in its course through the

inguinal canal and spermatic cord, it predisposes to an indirect hernia and to communicating hydrocele. The diagnosis of an inguinal hernia (Fig. 10b) is made on the basis of physical signs. The scrotal mass is soft, compressible, usually reducible and does not transilluminate. Auscultation may disclose peristaltic sounds or gurgling from intestinal contents. The presence of a communicating hydrocele (Fig. 10c) is not usually distinguished from a hydrocele of the tunica vaginalis testis until at operation a communication with the peritoneal cavity is found.

TRAUMA

Injury of the tunica vaginalis is nearly always caused by a blow to the scrotum. The response of the tunica may be the production of a large serous effusion known as a traumatic hydrocele (Fig. 10d). If the cavity becomes filled with blood it is known as a hematocele. A scrotal hematoma is a collection of blood in tissues outside the tunica. Acute hydrocele is similar to idiopathic hydrocele which will be discussed below. Spontaneous hematocele has been observed in arterial disease such as arteriosclerosis and in blood dyscrasias such as purpura. Traumatic lesions may or may not be painful.

Figure 10 Common lesions causing a mass in the scrotum.

Hematocele does not transilluminate. In addition, the blood may be under such tension that the surface feels stony hard and heavy, findings similar to those in tumor of the testis. The treatment of hematocele is surgical evacuation of the blood with excision or reflection of the tunica. Usually hematocele is evident in the history of trauma. In addition to tumor of the testis, differential diagnosis must be made from torsion of the spermatic cord and acute epididymitis.

IDIOPATHIC HYDROCELE

A hydrocele constitutes an abnormal accumulation of fluid in the tunica vaginalis testis (Fig 10d) or in an incompletely obliterated

drocele o lesion is the cause is usually unknown. Hydrocele is one of the most common causes of scrotal swelling. Small hydroceles are asymptomatic and go unrecognized by the patient. With large accumulations of fluid, the prevailing complaint is of a mass in the scrotum, sometimes with a dragging sensation. Occasionally hydroceles attain such tremendous size as to interfere with walking and sexual intercourse. The diagnosis is made on the basis of a symmetrical, cystic mass which is not tender. Hydrocele of the tunica vaginalis testis is confluent with the testis which is observed posterolaterally on transillumination of the scrotum. In hydrocele of the spermatic cord the testicle is felt apart from the cystic mass and in large hydrocele is displaced to the base of the scrotum.

A hydrocele of long standing may evoke fibrous tissue or calcification in the wall and fail to transmit light and thus be mistaken for neoplasm or hematocele. Elephantiasis of the scrotum is easily differentiated because the scrotal edema is bilateral and unaccompanied by a cystic mass within the scrotum.

Small hydroceles require no treatment. Those observed in infants and secondary to epididymitis may recede spontaneously. Whereas aspiration and injection of a sclerosing material has been attended with some success, this method of treatment may lead to infection and hemorrhage and is not recommended. Treatment should be surgical, either excising the parietal tunica vaginalis testis or reflecting it behind the testicle to prevent the reaccumulation of fluid. In addition to yielding a permanent cure, operation affords accurate examination of the scrotal

contents, ruling out any associated hernia, tumor or other abnormality.

SPERMATIC CORD

The spermatic cord is composed of the vas deferens, the artery of the testis, the epididymis, the pampiniform plexus, the lymphatics and the autonomic nervous supply. In addition there may be a patent or partially obliterated processus vaginalis which may lead to inguinal hernia or hydrocele of the cord.

The vas deferens extends from the epididymis to the inguinal canal and thence retroperitoneally to an ampulla before it joins the outlet of the seminal vesicle to form the ejaculatory duct.

ANOMALIES

Anomalies of the vas deferens consist either of an absence or aplasia of the structure which, if bilateral, accounts for isolated cases of sterility. These are an occasional accompaniment of renal agenesis or hypoplasia.

TRAUMA

Torsion of the spermatic cord (Fig 11) is produced by an axial rotation and the testicle is destroyed unless the torsion is promptly corrected by operation. As the cord twists, the blood supply to the testicle is diminished or completely cut off. As a rule, gangrene results. If there is not complete impairment to the circulation, a few spermatogenic cells survive, but atrophy is almost inevitable.

The condition is almost limited to boys

Figure 11. Torsion of spermatic cord causing gangrene of testis and epididymis.

nearing the age of puberty. It may occur in the cryptorchid testis as well as in the normally descended gonad. Although torsion is frequently attributed to a laxness of the tunica vaginalis testis, this is not always present. Torsion may take place within the tunica vaginalis (intravaginal torsion) or outside the tunica vaginalis (extravaginal torsion).

Rotation may be as minimal as a quarter-turn, although as many as five complete turns have been seen. Apparently the lesion is produced by a violent contraction of the cremaster muscle. Sometimes there is a history of strenuous physical activity, such as running or jumping, but in other instances, torsion develops as the patient lies quietly in bed. Rarely, torsion corrects itself spontaneously. Some patients experience recurrent attacks. Since the condition is likely to be bilateral, when operation is performed to correct torsion on one side, it is advisable to also suture the opposite testicle in place.

The typical onset of torsion is manifest by exquisite testicular pain and swelling. Abdominal pain, nausea and vomiting are common accompaniments. Rotation of the spermatic cord leads to elevation of the testicle, a valuable diagnostic sign. When untreated, the local process continues to cause acute symptoms for two or three days after which gangrene ensues with lessening of pain and relative anesthesia of the involved structures. Atrophy takes place over a period of several months.

A valuable diagnostic sign is that the testicle under torsion lies at a higher level

nosis is to mistake torsion for acute epididymitis. In the latter condition the urine usually contains pus cells and bacteria, and physical examination of the scrotum is of considerable help. In torsion it is impossible to make out a sulcus, as one can between an enlarged, tender epididymis and an uninvolved testis. The entire testicle is exquisitely tender and is palpated as one boggy or indurated mass.

Torsion of the appendix epididymis and appendix testis must also be considered in differential diagnosis. These may twist on their pedicles, producing a similar but more localized and less violent reaction. Soon after it occurs, torsion of an appendage produces a tender, indurated nubbun at the upper pole of the testicle; later, scrotal edema obscures this sign.

Since examination may be extremely painful in acute conditions, it is helpful to infiltrate the spermatic cord at the level of the external inguinal ring with a solution of 1 per cent Xylocaine. This relieves pain and makes it possible to palpate the structures in the scrotum. Aspiration of bloody fluid from the tunica vaginalis testis is a diagnostic sign of torsion. Blood is not present in epididymitis or orchitis. Whenever the diagnosis is in doubt, immediate exploratory operation is indicated. In torsion of the spermatic cord, immediate surgical correction offers the only hope of preserving the testicle. If operation is delayed more than three or four hours, atrophy is inevitable. In many cases, orchiectomy is necessary because of gangrene of the testicle.

INFECTION

Funiculitis, inflammation of the spermatic cord, is usually a complication of epididymitis or of vasitis. Acute funiculitis causes swelling of the cord with tenderness and induration. In chronic funiculitis the cord may be edematous and increase of connective tissue may suggest a mistaken diagnosis of hernia. Infection of the vas deferens extends upward from concurrent epididymitis below or downward from prostatic infection above. In the latter instance, if vasectomy has been performed, the process ends abruptly at the operative site, preventing extension to the epididymis. In acute vasitis there may be local tenderness, but this is mild in comparison to that in epididymitis and there is no febrile reaction from vasitis, as is usual in epididymitis. In chronic vasitis, the vas becomes fibrosed, beaded or nodular, the latter is common in tuberculosis.

NEOPLASM

Tumors of the spermatic cord are usually secondary to tumors of the testis. Primary tumors of the vas deferens are extremely rare. A few have been observed, similar to those of the epididymis.

VARICOCELE

Varicocele (Fig 10f) is characterized by elongation, dilation and tortuosity of the veins of the pampiniform plexus, usually on the left side. Most varicoceles are idiopathic and occur between the ages of fifteen and thirty-five years. Secondary varicocele results from obstruction to the spermatic vein by intra-abdominal tumors, particularly tumors of the kidney. Small varicoceles rarely give rise to symptoms. If large, they may

produce pain in the scrotum. Diagnosis is suspected on inspection, the wormlike configuration of the dilated veins being seen through the scrotal skin. This observation is confirmed by palpating enlarged, soft, dilated veins within the spermatic cord.

For asymptomatic varicocele, treatment is not indicated. When there is discomfort or pain, a snugly fitting scrotal suspensory may provide relief. Operation is indicated for large varicoceles which cause pain. The dilated segment of veins is excised and the testicle suspended by suturing the distal stump to the external inguinal ring.

INGUINAL LYMPHATICS

The inguinal lymphatics warrant consideration since they are intimately concerned with many of the lesions of the penis and scrotum. There are three groups of superficial inguinal lymph nodes which lie above and external to the saphenous opening. A deep group is situated around the femoral vein at the level of the saphenous opening. The lymphatics of the shaft of the penis, the penile skin and scrotum drain into the superficial inguinal lymph nodes, those of the urethra into the deep inguinal and hypogastric nodes and those from the glans penis to the external iliac nodes.

INGUINAL ADENITIS

Inguinal adenitis may be secondary to infections of the penis or scrotum. In an acute process, the nodes usually become enlarged and tender and the condition may progress to suppuration. In the chronic form, the nodes are discrete and painless. Suitable treatment of the local primary inflammation of the genitalia minimizes the development of secondary adenitis. Treatment of acute lymphadenitis consists of appropriate antimicrobial therapy, rest in bed and cold application to the affected areas. Chronic adenitis rarely requires treatment. Chancroidal bubo represents a lymphatic extension from a chancroid, usually on the penis. This lesion tends to suppurate and requires surgical drainage.

GRANULOMA INGUINALE

Granuloma inguinale is a superficial ulcerative skin lesion with complicating inguinal adenitis. The etiologic agent is an intracellular monocystic Donovan body transmitted by sexual contact. Although the lesion is prevalent in tropical areas, it has a low incidence in the United States. It is seen more frequently in the southern states and

in the Negro population. The lesion is essentially an indolent granuloma of the skin. There are usually multiple painless lesions. Advancing borders leave dense scars in their wake. Secondary infection is common. Diagnosis is made by finding the Donovan bodies in the smear of the exudate. Treatment consists of administration of streptomycin and tetracycline or their derivatives.

LYMPHOGANULOMA VENEREUM

Lymphogranuloma venereum (LGV) is a pathia (inflammation) of the lymphatic system (male) transmitted by sexual contact.

Blockage of the inguinal lymphatics may cause elephantiasis of the penis and scrotum. Diagnosis is suggested by inguinal adenitis and fistulas from involved lymph nodes. Confirmation is made by the intradermal Frei test and complement-fixation test. Although tetracycline is useful in treatment, surgical excision of the involved areas is frequently required when there is secondary infection.

METASTATIC NEOPLASM

Neoplastic invasion of the inguinal lymph nodes is a common sequela of carcinoma of the penis and of the scrotum. Differential diagnosis between lymphadenitis and carcinomatous invasion can be established by biopsy, since secondary infection is frequent in carcinoma of the genitals.

Since the lymphatic drainage of the penis and urethra is not only to the inguinal nodes but also, by a separate route, to the hypogastric and iliac groups of the pelvis, excision of the inguinal nodes is insufficient if "radical operation" is to be performed in carcinoma of these organs.

INTERNAL GENITALIA

The internal genitalia are the prostate, seminal vesicles and Cowper's glands. Their function is to provide secretions for storage of spermatozoa and to convey them during copulation. It has been estimated that the prostate and seminal plasma furnish extracellular nourishment for sperm, supplementing the intracellular nutritional reserve. Ninety-five per cent of a total volume of 2 to 4 ml. of spermatic fluid is provided by the prostate and seminal vesicles.

PROSTATE

The prostate (Fig. 12) is a musculoglandular body surrounding the vesical neck.

Through its central portion it transmits the posterior urethra; posteriorly it is perforated by the ejaculatory ducts. These open into the verumontanum on the floor of the prostatic urethra. The normal prostate weighs about 20 gm. and is roughly pyramidal. It lies deep within the pelvic cavity below the symphysis pubis, being supported anteriorly by the puboprostatic ligaments and inferiorly by the urogenital diaphragm. In the embryo the gland is derived from five epithelial evaginations of the posterior urethra which form into compound alveolar glands and empty into ducts opening into the posterior urethra.

The blood supply to the prostate is from the inferior vesical and internal pudendal arteries. The prostatic veins form plexuses about the sides of the gland and drain into the internal iliac veins. The nerves are derived from the pelvic plexus. The lymphatic drainage is into the nodes lying beside the external iliac and hypogastric blood vessels. There are intercommunications with the lymphatics of the bladder, seminal vesicles, vasa deferentia and rectum.

ANOMALIES

Of chief surgical interest are contraction of the vesical neck, valves of the posterior urethra, hypertrophy of the verumontanum, cysts of the prostate and mullerian duct cyst. The great danger is urinary obstruction, which may cause profound renal damage. The symptoms are similar to those of prostatic obstructions of later life. Treatment consists of surgical excision.

TRAUMA

Because of its protected position, the prostate is rarely injured. Injury may be caused by puncture or gunshot wounds and by inexperienced urethral instrumentation. In severe injury, treatment consists of immediate repair to avoid urethral stricture and permanent damage to the adjacent external urinary sphincter.

INFECTIONS

Infections of the prostate comprise a large portion of the problems encountered in the practice of urology. In view of an intimate association with the urethra and the vasa deferentia, the prostate is prone to infection from either of these sources. Less commonly infection is by way of the blood stream, the lymphatics or by direct extension.

Nonspecific Infection. From a surgical standpoint, the chief importance of the nonspecific infections is their coincidence with obstructive lesions of the prostate. Any obstructive lesion predisposes to infection and,

Figure 12 Anatomy and relationships of prostate.

once infection is established, it usually cannot be eradicated without first removing the obstruction. Any of the common pyogenic bacteria may infect the prostate either alone or in combination. *Escherichia coli* and other gram-negative bacilli are the most common invaders.

Acute prostatitis is an inflammation of the prostatic parenchyma, inevitably complicated by posterior urethritis. Unless there is co-incident obstruction, it may resolve without progression to chronic prostatitis or to abscess. In acute prostatitis, frequency and urgency of urination, nocturia and dysuria may be extreme. There may be hematuria and urethral discharge. The patient may complain of perineal aching or rectal or low back pain. Systemic symptoms of fever and, occasionally, chills occur. Inflammatory edema may lead to urinary retention. Digital examination reveals an exquisitely tender, enlarged prostate, usually firm. Examination of an acutely inflamed prostate should be most gentle. Massage may lead to epididymitis, bacteremia and severe systemic reaction.

Of chief importance in differential diagnosis is acute urinary infection, such as cystitis and pyelonephritis. The site of an acute infection is usually revealed by tenderness over the involved organ. Acute congestion of the prostate from retained secretion may lead to symptoms typical of prostatitis. The condition is due to lack of sexual intercourse or to sexual excitement which does not terminate in ejaculation. Since there is no bacterial invasion the patient is afebrile and the prostatic secretion is devoid of pus cells and bacteria.

Treatment of acute prostatitis consists of appropriate antimicrobial agents selected according to the results of microscopic and cultural studies of the urine, urethral discharge and prostatic secretion. Instrumentation other than the passage of a small urethral catheter to relieve urinary retention is contraindicated during the acute phase. Continuous catheter drainage is preferable to repeated catheterization, which is more injurious to the urethra and prostate.

Chronic prostatitis is usually either a sequela to acute prostatitis or is a complication of some prostatic obstruction. The condition may be asymptomatic. A few men complain of an aching pain or fullness in the perineum or of symptoms of mild vesical irritability. There may be a scant urethral discharge. Digital examination of the rectum may reveal a normal, boggy or an indurated prostate.

Epididymitis, either acute or chronic, may be a complication.

Diagnosis is established by the finding of pus cells, with or without bacteria, in the prostatic secretion. The chief error in differential diagnosis is in mistaking chronic, nonspecific urethritis for chronic prostatitis. The error is avoided by having the patient void prior to massage of the prostate. This removes any secretion from the urethra before prostatic secretion is expressed. Up to 5 per cent pus in the cellular elements of the prostatic secretion is a normal finding. Cystitis may be confused with prostatitis. Diseases of the anus and rectum may cause urinary symptoms and lead to the mistaken diagnosis of prostatitis.

Treatment of chronic nonspecific prostatitis should be directed to any contributory cause such as an obstructive process. Antimicrobial therapy is usually ineffective. Occasionally, judicious prostatic massage is helpful. This should be carried out no often-er than once a week or once every two weeks with the most gentle manipulation. Frequent massage injures the prostate and induces acute infection. Massage is contraindicated in the presence of prostatic calculi. The rationale of prostatic massage is that it dislodges cellular exudates which obstruct the prostatic ducts and impede drainage. Sexual intercourse encourages drainage without injuring the prostate.

Prostatic abscess is an occasional complication of acute prostatitis. Sometimes it can be recognized as a fluctuant area on rectal examination. Such an abscess may resolve, if small, or it may rupture spontaneously into the urethra. If not, prosta-totomy becomes necessary. Symptomatic treatment consists of analgesics, hot sitz baths and bed rest. Fluids should not be forced unless an indwelling urethral catheter is in place, because frequent voiding causes irritability of the bladder and urethra.

Tuberculous prostatitis is usually secondary to tuberculosis of the kidney. The symptoms are generally overshadowed by the symptoms of involvement of the urinary tract: dysuria, frequency of urination and hematuria. On rectal examination the prostate is found to be markedly indurated. It may be stony hard, suggesting carcinoma. However, in contrast to carcinoma, the condition usually occurs in the young. Differentiation is made by the finding of tubercle bacilli in the urine and the recognition of tuberculosis elsewhere in the urogenital

tract. Tuberculous prostatitis usually responds promptly to chemotherapy. Excision of the prostate and seminal vesicles is no longer indicated.

PROSTATIC ENLARGEMENTS

Since the prostate completely surrounds the posterior urethra, any abnormality of this gland is a potential source of urinary obstruction. Some pathologic conditions are more likely to produce obstruction than others. Lesions such as benign hyperplasia progress slowly. Others, such as acute prostatitis, cause only temporary obstruction and still others, such as prostatic calculi, are less prone to cause obstruction. Prostatism is a clinical term which refers to the symptomatic and pathologic complex which results from any obstruction at the vesical neck. The symptoms and diagnostic measures are quite similar for the different lesions. Symptoms fall roughly into four groups:

1. *Obstructive symptoms* The symptoms of mechanical obstruction are caused by encroachment on the vesical neck and by the reaction of the bladder to obstruction. Noc-

turia is usually the earliest symptom and in most instances serves as a rough index of the stage of a lesion. Less noticeable but occurring with nocturia are diurnal frequency of urination and a diminution in the size and force of the urinary stream. Later, there are hesitancy and dribbling on urination, urgency of urination and incontinence. Hematuria may be another symptom of obstruction. The force exercised during difficult urination incites bleeding. With the development of residual urine, the patient may note a mass low in the abdomen and have a feeling of incomplete emptying of the bladder. Complete obstruction may supervene.

2. *Symptoms of superimposed infection.* When an obstruction is complicated by acute urinary infection, all previous symptoms exacerbate markedly.

3. *Uremic symptoms.* In some instances the symptoms of azotemia, secondary to hydronephrosis, are the first to call attention to a lower urinary obstruction.

4. *Sexual symptoms.* Some patients with prostatic enlargement have increased potency, in others, it is diminished. As a general

rule, decreased potency is a more frequent accompaniment of carcinoma of the prostate than of a benign lesion.

Obstructions to the vesical neck impede the outflow of urine leading to back-pressure changes in the bladder—hypertrophy of the trigone, trabeculation of the detrusor, the formation of cellulæ and diverticula. During an initial stage of compensation, the capacity of the bladder becomes decreased to 250 ml. or less. Later the kidney is destroyed by hydronephrosis caused by compression of the intramural portion of the ureter by the hypertrophied bladder musculature. Later, with decompensation, the bladder becomes widely distended, to 1000 ml. or more, and overflow incontinence results.

As a part of the study of the patient with prostatic obstruction, kidney function tests are necessary to reveal whether there has been any impairment of renal function. Intravenous urograms are obtained, if renal function is adequate, to learn the condition of the kidneys, ureter and bladder. The after-voiding film will show residual urine without the danger of introducing infection, which accompanies catheterization.

Benign Hyperplasia of Prostate. Of all obstructions which arise from the prostate, benign hyperplasia is the most common, occurring in over 50 per cent of men past the age of fifty and 75 per cent of those past eighty years of age. Although the cause of benign hyperplasia remains in doubt, some hormonal imbalance seems to be either a predisposing or aggravating factor. In con-

tradistinction to carcinoma of the prostate, which arises from the prostatic cortex, benign hyperplasia arises from the glandular acini in the immediate vicinity of the mucosa of the prostatic urethra (Fig. 13). For this reason it is more logically referred to as periurethral adenoma than benign prostatic hyperplasia. It is not a neoplasm, but is an overgrowth of normal glandular and muscular elements. As prostatic hyperplasia progresses, the true glands of the prostate are compressed peripherally. Between the two a plane of cleavage develops, known as the surgical capsule, a plane which permits the surgeon to shell out a periurethral adenoma from within the prostate at open operation (Fig. 14).

Benign prostatic hyperplasia is referred to according to the location of hyperplastic glands. Median lobe and lateral lobe enlargements are the most common (Fig. 15). On rectal examination in lateral lobe hyperplasia the gland is symmetrical and elastic throughout. In median lobe hyperplasia the findings may be confined to the vesical side and are established only by cystourethroscopy and cystourethrography. Treatment is surgical, removing the hyperplastic adenoma. Large adenomas are to be removed by open operation, small adenomas by transurethral prostatectomy. In conservative prostatectomy, only enlargements within the prostate or at the vesical neck are removed (Fig. 16). The true prostatic tissue is left in place.

Median Bar. Next in frequency of occurrence of benign hyperplasia is median bar (Fig. 15). This lesion develops in a younger

age group than does the former. The lesion is a fibromuscular elevation of the posterior vesical lip which distorts the normally smooth vesicourethral outlet. The bar is separate from the prostate. Although it has been said to be secondary to prostatitis, in most cases of median bar, prostatic tissue is normal. When a rim of fibrous tissue completely encircles the vesical neck, the condition is contracture of the vesical neck. This may be congenital or secondary to infection or to prostatectomy. The diagnosis of both these lesions is established by cystourethroscopy.

Carcinoma of Prostate. Of the prostatic neoplasms, adenocarcinoma is the most common. It has been estimated that 15 per cent of all men over fifty years of age develop cancer of the prostate. However, many carcinomas are small and do not come to clinical recognition. Like most neoplasms, prostatic carcinoma has no known cause. It develops in the cortex of the prostate, whereas benign hyperplasia develops immediately around the urethra (Fig. 13). Its progress is so slow that by the time it produces symptoms of obstruction to the outflow of urine, metastasis has occurred in many cases. Lesions amenable to surgical cure are those discov-

ered as incidental findings on routine rectal examination or those that occur with benign prostatic hyperplasia which leads to their discovery. The earliest sign on rectal examination is a stony-hard area within the prostate. If it lies superficial to the rectal surface, palpation usually reveals irregularity (Fig. 13). In advanced carcinoma the prostate becomes fixed and there is asymmetric involvement of the entire gland (Fig. 13). Typical areas of invasion are to the seminal vesicles, the base of the bladder and the membranous urethra.

Carcinoma of the prostate spreads both by way of the lymphatics and the blood stream, the latter giving rise to osseous metastasis most frequently in the lumbosacral spine, the bony pelvis and upper portions of the femur. Osseous metastasis causes pain when the body is immobile, whereas lumbosacral pains caused by arthritis usually cease when the patient is quiet. Invasion of perineural lymphatics accounts for pain along the course of the sciatic nerves on the posterior aspects of the thighs.

A peculiar feature of prostatic tissue is the production of a large quantity of enzyme known as acid phosphatase. In the normal

prostate most of this enzyme drains into the urethra and is carried off in the urine so that the blood level remains low. When enormous quantities are produced, blood acid phosphatase becomes elevated, indicating metastatic carcinoma of the prostate. Since the blood acid phosphatase in all metastatic carcinomas is not elevated, a negative finding does not rule out dissemination. A source of error in this test is in obtaining blood for examination within forty-eight hours of prostatic massage, a manipulation which will carry the enzyme into the blood stream from the normal prostate.

Differential diagnosis must be made from chronic prostatitis, either nonspecific or tuberculous, with fibrous tissue reaction which may simulate the stony-hard induration of carcinoma. Also, areas of calcification or calculi may yield rectal findings suggestive of carcinoma. The ultimate diagnosis, particularly in early cases amenable to surgical cure, is made by biopsy. This is usually best accomplished after perineal exposure of

the gland when tissue is examined by frozen section. If the diagnosis proves positive, immediate prostatovesiculectomy is carried out at the same time. In advanced cases the diagnosis usually presents little difficulty. In addition to the typical rectal findings there is frequent elevation of the blood acid phosphatase and osseous metastasis. However, even in advanced cases, it is important to establish the diagnosis with certainty before starting treatment. This can be done by needle biopsy through the perineum or by transurethral resection of tissue.

With respect to treatment, the only known cure is by complete surgical extirpation, i.e., total prostatovesiculectomy (Fig. 17). However, the outlook in patients with advanced carcinoma of the prostate has been remarkably brightened by hormonal therapy. In 1947 Huggins made the epic-making discovery that castration and/or the administration of estrogen favorably influences the course in 80 to 90 per cent of all cases. Estrogen suppresses the function of androgen-forming

cells of the testis, which promote activity of prostatic carcinoma. Although the effect of neoplastic stimulation has been abundantly proved, it has never been demonstrated that androgens initiate carcinoma of the prostate. With removal of androgen stimulation, there is a cessation or regression in many patients, to such an extent that the rectal signs of carcinoma entirely recede. Likewise the blood acid phosphatase activity is suppressed and osseous metastasis recedes. Unfortunately, although patients may obtain relief for periods of several months or several years, there is a tendency sooner or later for the carcinoma to escape from hormonal control, either with estrogens alone or castration alone, or with both. Apparently the use of both methods is the most advisable.

After escape of the carcinoma from hormonal control, other measures may be applied, such as administration of tremendous dosages of estrogens or the use of adrenal steroid hormones. At this stage androgens occasionally prove beneficial. Neither hypophysectomy nor adrenalectomy has proved its worth in treatment of prostatic carcinoma although both operations have been helpful in isolated instances.

When advanced carcinoma of the prostate does not yield to conservative measures, transurethral resection of obstructing tissue is indicated. It must be remembered that if there is coincident hyperplasia of the prostate, a fairly common association, treatment directed to carcinoma will not relieve the obstruction of benign hyperplasia.

RADICAL PROSTATECTOMY

Figure 17. Total prostatovesiculectomy for carcinoma of the prostate, removal of prostate, seminal vesicles and surrounding fascia: A, retropubic route. B, perineal route.

Sarcoma and secondary neoplasms, such as invasion of carcinoma of the rectum, are less common and usually can be treated only by palliative resection and symptomatic treatment.

Prostatic Calculi. Calculi sometimes form in the glandular acini and ducts of the prostate. With growth, they assume the contour of the units in which they lie. They may involve segments on one or both sides, or the entire gland. Large calculi impart a stony hardness to the prostate, observed on rectal examination, occasionally they yield crepitation. Diagnosis is established by demonstrat-

Figure 18. X-ray showing prostatic calculi which have assumed conformation of prostatic ducts

ing their presence on x-ray of the prostatic region (Fig. 18)

From a clinical standpoint, calculi are of threefold significance: (1) they may lead to the mistaken diagnosis of carcinoma, (2) they frequently occur in association with obstructive processes, as benign hyperplasia and carcinoma of the prostate, and (3) calculi themselves may cause urinary obstruction or contribute to infection and thus provide indication for operation. If they are asymptomatic and do not produce urinary obstruction or contribute to infection, no treatment is indicated

SEMINAL VESICLES

The seminal vesicles are a pair of monotubular structures located just above the prostate between the floor of the bladder and the rectum. Joined medially by the ampullae of the vasa deferentia, they unite to form the ejaculatory ducts (Fig. 1). The function of the seminal vesicles is to secrete a tenacious mucus and serve as a reservoir for spermatic fluid. Their muscular wall contracts during ejaculation to expel secretion.

The intimate relationship of the seminal vesicles to the vesical trigone, the prostate, the posterior urethra and the rectum explains why seminal vesiculitis, the condition of most surgical concern, may cause urinary frequency, dysuria and painful defecation.

ANOMALIES

Congenital anomalies of the seminal vesicles usually accompany ipsilateral maldevelopment of the upper urinary tract. They are extremely rare and of little clinical importance.

TRAUMA

Injuries of the seminal vesicles are likewise extremely rare. They are usually a complication of fracture of the bony pelvis. Treatment is the same as for trauma to the prostate.

INFECTION

Inflammation of the seminal vesicles is usually with pyogenic bacteria secondary to infection of the posterior urethra and prostate. Failure to recognize seminal vesiculitis may lead to confusion in explaining obscure symptoms of low backache, perineal discomfort and urinary irritability. Perhaps one important cause of continued difficulty from seminal vesiculitis is occlusion of the ejaculatory duct which prevents escape of infected products.

Acute seminal vesiculitis is readily diagnosed by the palpation of an enlarged tender seminal vesicle, an oblong-shaped, cystic mass above the prostate. In chronic seminal vesiculitis, the seminal vesicle becomes indurated and fixed. Diagnosis can sometimes be established by stripping the seminal vesicle and recovering vesicle fluid impregnated with pus cells and bacteria. The treatment is as for prostatitis. In chronic infection, gentle stripping of the vesicles may induce resolution of the process. Occasionally in chronic infection, seminal vesiculectomy becomes indicated. Since this operation may produce sexual impotence, it should not be lightly considered in young men.

NEOPLASMS

Fewer than thirty cases of carcinoma of the seminal vesicles have been reported. The growth of the neoplasm is so rapid as to make it difficult to determine the site of origin. Secondary invasion of the seminal vesicles by carcinoma of the prostate by way of the perineural lymphatics is quite common. Extension is revealed by rectal palpation.

COWPER'S GLANDS

The bulbomembranous glands of Cowper are paired glands between the layers of the urogenital diaphragm, which drain by ducts which empty into the floor of the bulbous urethra (Fig. 1). They provide a clear, alkaline, mucoid secretion which supplements the spermatic fluid. This secretion apparently alkalizes the urethral channel to prepare the way for expulsion of semen. In the normal state, Cowper's glands are not palpable. When they become infected, they enlarge and, on rectal examination, can be palpated adjacent to and lateral to the membranous urethra. Sometimes pressure over an infected gland yields pus from the urethra.

DIFFUSE ANOMALIES AFFECTING REPRODUCTIVE SYSTEM

SEXUAL IMPOTENCE

Impotence signifies the inability to perform properly the sexual act. This may be manifest by a loss of libido, by the inability to gain or to sustain an erection or by difficulties related to ejaculation. The mechanism of coitus entails a complex coordination of nervous, vascular, muscular and chemohormonal influences. When any or all of these factors are deficient, impotence may de-

velop. It has been estimated that impotence affects between 25 to 35 per cent of all adult males.

In 90 to 95 per cent of men complaining of impotence, the inadequacy is emotional rather than physical. The practice of withdrawal as a means of preventing pregnancy is sometimes the sole cause. Psychogenic influences which lead to impotence are guilt, anxiety or jealousy, or of frigidity of the female partner. Common among the neurogenic causes are tabes dorsalis, hemiplegia, multiple sclerosis and other diseases affecting the spinal cord. Damaging both the nerves and vascular supply to the penis are extensive pelvic operations, as for carcinoma of the rectum or prostate. Purely vascular causes are coarctation of the abdominal aorta. A chemohormonal cause of impotence is absence of both testes, either congenital or traumatic. Atrophic testes usually provide adequate androgen to establish secondary sex characteristics and to perform coitus despite defective spermatogenesis. In Cushing's disease, impotence may result from decreased gonadotropic activity and loss of androgen secretion. Bilateral orchiectomy performed after puberty sometimes, but not universally, produces impotence. The administration of estrogens, as in the treatment of carcinoma of the prostate, almost invariably produces impotence because of the inhibitory effect on the pituitary gland. Patients with pituitary adenogenital syndrome do not develop secondary sex characters and are impotent. Impotence may also develop in profound systemic disorders, febrile and cachectic states.

With respect to the local causes of impotence, congestion and infection of the prostate, prostatic urethra and verumontanum tend to produce premature ejaculation, apparently because of mechanical irritation. Carcinoma of the prostate may produce impotence, particularly in the advanced stages. It is obvious that almost all lesions of the penis may either cause or contribute to impotence.

In the study of a patient with impotence, the examination must be sufficiently complete to differentiate between systemic, local, organic, and psychologic causes, for without accurate diagnosis, treatment cannot be intelligently administered. Cystourethroscopy should be a part of the examination to disclose any abnormality of the vesical neck or posterior urethra. Treatment is directed to the cause. In most young males, this is psychiatric. Since sexual problems are

among the most difficult to treat, they usually require more skill than the physician without psychiatric training can give.

INFERTILITY

Fertility is the capacity to procreate. Infertility signifies impairment of a normal capacity to produce offspring. With complete and permanent incapacity, the condition is known as sterility. Studies indicate that the male is the sole cause of infertility in 20 to 40 per cent of all barren marriages. The fertility of the male is learned through studies of the spermatic fluid, including the number of spermatozoa, the percentage of abnormal forms and their viability. If sperms are absent or defective, biopsy of the testis is indicated to differentiate between the types of intrinsic deficiency of the germ cells. This study will also reveal cases in which there is normal spermatogenesis and azospermia caused by obstruction to the conductive system.

The causes of male infertility are one or more of the following factors:

1. Deficiencies in the manufacture of germ cells: It has been estimated that 95 per cent of infertile males suffer from intrinsic spermatogenic defects. The germ cells of the seminiferous tubules may be congenitally defective, they may have been damaged by infection, as in mumps orchitis, or by trauma, as in destruction of the blood supply, or the defect may be chemohormonal, as in hypopituitarism. The cryptorchid testis is almost invariably deficient in spermatogenesis. Although this was previously presumed to be due to damage from increased temperature in the undescended position, the inability to restore normal spermatogenesis by orchiopexy, no matter how early in life the operation is performed, suggests that the possible defect may be congenital.

2. Obstructions to the conductive system. The usual cause of this defect is bilateral stenosis due to epididymitis, usually gonococcal. Occasionally there is congenital absence of the vas deferens. This excludes acquired defects, such as bilateral vasectomy.

3. The inability to perform the normal sexual act. Obviously the impotent male has difficulty in the delivery of spermatozoa, although his capacity to produce normal spermatozoa may not be impaired. Thus, the patient may be impotent yet fertile or he may be potent yet sterile.

In the clinical study of a patient complaining of inability to reproduce, a careful history should be taken of all possible eti-

ologic factors, such as mumps orchitis, tuberculosis, deficiency diseases, operations such as repair of inguinal hernia or orchiopexy, trauma to the genitalia and genital infections such as epididymitis. The patient should be questioned about the course of any pregnancies he has induced and about his performance of the sexual act.

Physical examination should be painstaking, seeking out any neurologic cause or endocrine dyscrasia. Careful examination should be made of the genitalia with particular attention to the prostate, seminal vesicles, vasa deferentia, epididymides and testes. In obscure cases, cystourethroscopy should be carried out to seek any abnormality of the posterior urethra or verumontanum. The urine and prostatic secretion should be examined for pus cells which would indicate a complicating infection.

The most important step in the study of a patient of suspected infertility is examination of the spermatic fluid. Care should be taken in collection to avoid contamination with chemicals such as those that might be present on a condom. The best specimen is produced by masturbation following four days of abstinence from intercourse. Examination should be made within a few hours after collection to learn of the motility of the spermatozoa. In addition to a total count, the percentage of defective forms should be calculated. Testicular biopsy provides the final information concerning spermatogenesis, giving indication of the degree and type of any impairment.

The results of treatment of infertility in the male are not encouraging. General measures should be instituted to improve the general health. Frequently, when infertility is mild, a vacation supplemented by rest and an adequate diet will produce the desired result. Sexual technique should be discussed with the patient. Frequently the timing of intercourse to the period of fertility in the female will prove successful. Intercourse at this time should be carried out after three or four days of celibacy, since this helps increase the number and vigor of spermatozoa. In overweight men, a reducing diet should be prescribed. Vitamin D preparations help the liver to inactivate estrogens.

Of the various forms of hormonal therapy, thyroid has proved most effective, particularly in cases of hypothyroidism. Gonadotropins would theoretically aid the development of the seminiferous tubules, but their use has not proved successful, perhaps because preparations thus far developed are

not sufficiently powerful. Androgens are contraindicated since they depress rather than stimulate spermatogenesis. There is one exception to this rule in that the rebound following administration of testosterone has proved effective in some instances. In this method, testosterone is given for three to six months, providing there is no blockage to the conductive system. Following cessation of treatment, a rebound may result in increased spermatogenesis.

Vasovasostomy in cases of previous vasoligation will result in success in 60 to 80 per cent, when the operation is performed bilaterally. Epididymovasostomy, if azoospermia is caused by occlusion of the ducts in the globus minor, has a very low rate of cure. This operation attempts to divert sperm from the globus minor of the epididymis to the vas deferens. Technically the operation leaves much to be desired and it may be followed by stenosis. The possibility of restoration of fertility in bilateral cryptorchism by bringing both undescended testes into the scrotum is of questionable value, even if the operation is performed early in life. After puberty there is no chance of restoration of spermatogenesis.

INTERSEX STATES

These conditions produce external manifestations of both sexes to an abnormal degree. Hermaphroditism makes it difficult or impossible to determine on external inspection the sex of the patient. The entire appearance such as the breasts, distribution of hair, shape of the body and tone of the voice may suggest the sex opposite the one represented by the gonads. Deformities of the external genitalia which throw doubt upon the true sex of the individual should be recognized during childhood. Temporarily is not only disastrous to the emotional balance of the child but may contribute to omission of appropriate forms of therapy.

FEMALE PSEUDOHERMAPHRODISIS

This condition, also known as congenital adrenogenital syndrome, is caused by prenatal hyperplasia of adrenocortical tissue. The patient has normal ovaries, uterus, fallopian tubes and vagina; however, the vagina usually communicates with the urethra, which, in turn, opens at the base of an enlarged clitoris that may resemble a penis. The labia are often hypertrophied, simulating a bifid scrotum. The external appearance thus simulates perineal hypospadias with cryptorchism.

In many instances the diagnosis of the true condition rests upon abdominal exploration and biopsy of any gonadal tissue. Gonadal sex can be ascertained also by microscopic study of the cells in a skin biopsy or vaginal or buccal smear, estimating the percentage of female cells which have large chromosomes. If 70 per cent or more of the cells contain this chromosome, the sex is female. If less than 10 per cent are positive, the sex is male. Female pseudohermaphrodites usually adjust best as females. Patients seen in infancy and treated with cortisone may achieve normal female development. If the clitoris remains large, excision of this structure is to be considered, as is separation of the urethra from the vaginal tract so that both open on the perineum.

MALE PSEUDOHERMAPHRODISM

In male pseudohermaphroditism the testicles are developed, but development of the external genitalia is incomplete. Perineal hypospadias with bifid scrotum is a form of male pseudohermaphroditism. Strictly speaking, even mild hypospadias presents a form of intersexuality. In marked male pseudohermaphroditism, the external genitalia may closely simulate the female type. Diagnosis is made by observing testicles in the groin, a short vagina and the male sex chromatin in skin biopsy or buccal smear, or by surgical exploration. These children are reared most successfully as girls. Since the testicles are sometimes painful and provide a source of embarrassment in later life, orchiectomy is indicated. Estrogen therapy is begun at puberty to accentuate the female characteristics.

TRUE HERMAPHRODISM

True hermaphroditism is extremely rare. It may be manifest as one ovary and one testis on either or both sides or an ovotestis on either or both sides. Surgical correction is directed toward establishing the sex to which the patient seems most inclined, removing the opposite gonadal tissue. Usually the external genitalia can be converted to the one or the other sex by appropriate surgical measures.

HYPOGONADISM IN THE MALE

Since the hormones derived from the testes have little influence on development until after puberty, the effects of male hypogonadism first become apparent after puberty. However, causative lesions are often congenital and may be discovered in

early life. Sexual infantilism or hypogonitalism is identified by a disproportionate smallness of the external genitalia in relation to the general bodily development. It may result from primary testicular hypoplasia or from destructive diseases of the anterior pituitary lobe. There is frequently associated thyroid and/or adrenal deficiency. Pituitary infantilism is commonly known as Fröhlich's syndrome. Turner's syndrome is characterized by testes of normal size, yet histologically spermatogenic cells are arrested and the penis and prostate are hypoplastic. Klinefelter's syndrome is characterized by small testes. Eunuchoidism is caused by bilateral congenital absence or hypoplasia of the testes.

SEXUAL PRECOCITY

Adrenocortical hyperplasia is the most common cause of precocious sexual development in the male. The external genitalia may be noticeably enlarged at birth and at times a mild degree of hypospadias is present. Cortical tumors of the adrenal produce a similar precocity. Since the action of the hormone is only upon the secondary sex characteristics, there is a lack of simultaneous spermatogenesis.
